(6) "If it consists in whole or in part of a filthy, decomposed, or putrid animal or vegetable substance or any portion of an animal unfit for food, whether manufactured or not, or if it is the product of a diseased animal or one that has died otherwise than by slaughter." Examples: oysters contaminated with sewage; eggs known as "rots and spots"; animals which have died otherwise than by slaughter; figs containing an excessive quantity of worms and worm excrement. This paragraph of the law has caused much discussion, especially the meaning of the word "decomposed." This question is considered more in detail under the paragraph Decomposed Foods.

*Misbranding.*—The term "misbranding" is specifically defined in the Food and Drugs Act and provides for all possible conditions of fraud, mislabeling, imitation, substitution, and other forms of deception. Misbranding is regarded as a form of adulteration under the Food and Drugs Act. The practices of misbranding under any circumstances are so evidently fraudulent or dishonest that they cannot be justified on any score and are wholly condemned. It is true that many instances of misbranding do not directly affect health, except in so far as they deceive the consumer; that is, he is purchasing at a high price an article which contains less nutritive value than claimed for it. An honest label which correctly states the character, origin, amount, and the constituent parts of an article is as much a desideratum in food products as it is in commercial articles of all kinds. Honest labeling is the heart and soul of the pure food movement.

## PRESERVATION OF FOODS

The preservation of meat, milk, vegetables, and other perishable foods is one of the most important questions we have to deal with in the whole range of hygiene. Fermented and decayed foods must be looked upon with suspicion. The proper preservation of foodstuffs

involves not only the art of keeping them "fresh" and wholesome, but also keeping them so that they will not lose their nutritive value. Finally, foodstuffs must be preserved so that they will not acquire injurious properties. The preservatives ordinarily in use are: cold, drying, salting, smoking, canning, preserving, and chemical treatment. The best are *heat, cold and drying*.

Practically all these methods have long been in use. The only modern innovation in the preservation of foods is in the perfection of the old processes, based upon our knowledge of antiseptics and germicides. Heat and cold represent old family methods which have been extended and improved in the modern canning and cold storage industries. The drying of fruits, fish, and meats is a practice of very ancient origin. The use of salt doubtless antedates all historical records. Sugar either alone or with acetic acid in the form of vinegar and with various spices is an old contrivance and well known everywhere. The application of creosote obtained crudely from the smoke of incompletely burned wood is the ancient forerunner of some of the modern packing processes.

Concerning the value and legitimacy of these old family methods there is comparatively little difference of opinion; salt meat is not as good as the fresh article; dry apples do not make the best apple pie; chipped beef is not an adequate substitute for a fresh steak. However, it is absolutely necessary to preserve food in some way in order to tide over the winter or the dry seasons, to furnish food to people living and working in desert and arid regions, and to feed the hordes of people massed together in great cities. It would be impossible to maintain the large population of a modern metropolis if it were dependent upon a daily supply of fresh food materials.

The art of preserving foods depends upon the science of bacteriology. A more complete knowledge of the causes of decomposition and methods by which they may be prevented has enabled us to perfect the crude and primitive methods that have been in use from time immemorial, so that it is now possible to preserve certain foods practically indefinitely without in any way injuring their nutritive value or seriously interfering with their appearance and taste.

The chief harm has come from the blind use of chemical germicides, without regard for their harmful properties. The simplest and cheapest way to preserve food is by adding one of these chemicals, and the method was, therefore, seized upon by alert men whose chief interest was of the pecuniary kind. The question was to find the smallest percentage of a chemical which would prevent the decay of some particular food product, trusting to luck that the preservative used might prove harmless to the consumer. Often these chemicals were added with a liberal hand; further, it was soon found that chemical

preservatives could be used to preserve food products for the market from materials already so decayed as to be unsalable in their original condition.

The National Pure Food and Drugs Act of 1906 was passed largely to meet this situation. This law considers any food which contains some "added poisons or other deleterious ingredient which may render such article injurious to health" as adulterated. To Harvey W. Wiley belongs the credit of inducing Congress to pass this legislation against opposition and for an aggressive administration that proved useful in bringing the whole question prominently before the public.

**Cold.**—Cold must be regarded by the sanitarian as an antiseptic rather than a germicide. Low temperatures kill few bacteria, but prevent the growth and multiplication of most of them. Even the antiseptic properties of cold are not as marked as they were once believed to have been. Many plants and even frogs may survive freezing.

Some bacteria grow and multiply at low temperatures, even at 0° C. In 1871 Burdon-Sanderson was the first to show that freezing does not kill bacteria. Von Frisch demonstrated that subjecting a putrefying solution to a temperature of -87° C. for some hours did not affect sterilization. Leidy in 1848 showed that water derived from melted ice contained not only living infusoria, but also rotifers and worms. Pictet and Young found that anthrax and symptomatic anthrax cultures were not killed after an exposure of 108 hours to -70° C. Later Macfadyen proved that the temperature of liquid air does not kill bacteria; he subjected cultures to temperatures of -315° F. Ehrlich has shown that cancer cells kept cold will live and remain virulent for at least two years.

While no microorganism pathogenic for man will grow and multiply at the low temperatures of the refrigerator, there are a number of saprophytic bacteria and molds that develop abundantly at temperatures as low as 0° C. Milk, meat, eggs, and other products kept in cold storage at or near the freezing point may show a notable increase in the number of bacteria. A number of tests made in my laboratory showed that in the case of milk these low-temperature microorganisms belong mainly to the putrefying and proteolytic group. They produce an alkaline reaction in the milk and a bitter taste. Whether they are capable of forming poisonous products at these low temperatures is doubtful.

For the most part pathogenic bacteria withstand freezing temperatures. They, however, suffer a quantitative reduction when frozen (see Ice and the effects of freezing upon bacteria, page 1185). Most animal parasites die in cold storage; a few, however, survive. The length of time the material has been refrigerated is an important factor. Just as infected water becomes safer by storing it, so with foods. Cold storage

renders foods safer, but cannot be entirely relied upon for all infections. Time is the important factor, but the degree of refrigeration also influences the length of time a parasite will remain alive. Thus, *Trichinae* die at or below 5° C. in twenty days. If the temperature is maintained at 15° F. or below, the larvae of *T. saginata* (the beef tapeworm) are killed within 6 days, and there are indications that the larvae of *T. solium* (the pork tapeworm) would be killed in a similar length of time at the same temperature.

Fortunately, cold causes a quantitative reduction in the number of harmful bacteria, even though it does not produce complete sterilization. The element of time here plays an important rôle, as most of the surviving pathogenic microorganisms soon die. From a sanitary standpoint the protection afforded by refrigeration is reassuring, although not perfect. Cold acts as a preservative for some viruses.

The best temperature at which foodstuffs may be kept must be determined for each case. Some substances, such as meat and poultry, are better preserved when actually frozen; others, such as shell-eggs or milk, are materially injured by freezing. Fish are usually frozen. They are then dipped in water and refrozen in order that they may be completely encased in ice. They are then stored at a temperature of -16° C. The coating of ice, which is renewed as occasion requires, prevents loss of water due to surface evaporation. Under these circumstances there is no evidence whatever of any depreciation in the nutritive value or any change in the sanitary character of the fish at any time during two years of cold storage.<sup>64</sup>

In any event, the temperature of the icebox should not rise above 7° C. At this temperature bacterial growth does not entirely cease, although very markedly hindered. Few household refrigerators reach this temperature or maintain it for any length of time—either through faulty construction or on account of insufficient ice. Often the icebox is placed in a sunny corner, or, for convenience, near the kitchen stove. The doors of the ice chest frequently do not fit well, which results in needless waste and imperfect refrigeration. A study of household refrigerators discloses the fact that the temperature is often 15° C. and higher. Such conditions make good incubators, favoring bacterial growth. *B. enteritidis* will grow at 10° C. The necessity for scrupulous cleanliness, aëration, and dryness in all refrigerating devices needs only be mentioned.

In ordinary refrigerating plants moisture condenses on the surface of the objects exposed. In the case of meat this moisture dissolves some of the proteins, extractives, and salts, and makes a perfect culture medium for bacteria and molds. In the case of meats it is, therefore, better to hang them in a current of dry, clean air, in order to

<sup>64</sup>Smith, C. S.: *Biochem. Bull.*, 1913, III, 54.

desiccate the surface, before they are placed in the refrigerator. The dried surface delays the inward growth of the inevitable bacterial contamination upon the surface.

Articles of food may be kept in a satisfactory condition in cold storage for a very long time. The time varies with the article and its condition when placed in storage, also with the temperature and other factors. A striking illustration of the great preserving power of low temperatures occurred several years ago in Northern Siberia. In consequence of a great landslide on the banks of the Kolyma, the head of a mammoth became exposed and was so well preserved that even the fleshy trunk remained. It is said that famished wolves and half-starved natives began to eat of the flesh. The Russian government sent Dr. Hertz to rescue what remained. The mammoth had remained in cold storage perhaps thousands of years. Some of the soft parts are now preserved in the Museum at Petrograd. This must not be taken as justification of prolonged storage or the "cornering" of foods for economic gain in mammoth cold storage warehouses. While meat, poultry, eggs, and vegetables may be kept in a satisfactory condition for months and transported over seas, cold storage need not be unduly prolonged. In any case, the consumer is entitled to know whether the article is fresh or stored, and the time it has been in cold storage. These facts should be stated upon the label or stamp.

The question of cold storage poultry was investigated by the Massachusetts State Board of Health, and the conclusion was reached that it made practically no difference whether the fowl were drawn or not, but that they must be perfectly fresh when placed in cold storage. Poultry is kept below 0° C., at which temperature no noticeable change occurs. It was found that cold storage fowl are even less contaminated with bacteria than freshly killed birds that have hung for a few days. However, the cold storage animals, when removed from the refrigerator, decompose more quickly than the fresh.

Contrary to what might be expected, drawn poultry decomposes more rapidly after removal from cold storage than undrawn. This is because in the process of drawing the intestines are broken below the gizzard and the carcass becomes badly contaminated with intestinal bacteria. If the entire alimentary canal, esophagus, crop, gizzard, and intestines are removed intact, and with bacteriologic care to prevent contamination, the bird is practically safe from putrefaction.

From a sanitary standpoint, then, refrigeration is one of the best methods of preserving foodstuffs. The advantages of cold as a preservative are that it neither adds any constituent to the food nor takes away any constituent from the food. Cold imparts no new taste, nor does it seriously alter the natural flavor. It does not diminish its digestibility nor cause a loss of nutritive value. The material is left in approxi-

mately its original condition. Cold may, therefore, be regarded as one of the simplest and best antiseptics we have for the preservation of foods. It is now almost universally applied to prevent decomposition and decay. The housewife uses it to keep food in cold cellars, deep wells, and the like. During the last fifty years the use of ice for the purpose of refrigeration has become commonplace. Fresh and wholesome food may now be transported to the tropics, and the sustenance of large communities in insular and arid regions is made possible and pleasurable through the preserving use of cold.

**Drying.**—Drying, desiccation, or evaporation is a favorite and primitive method of preserving meats, fruits, vegetables, and various food materials. Dryness furnishes ideal antiseptic conditions. Microorganisms must have moisture to grow and multiply. Most pathogenic microorganisms soon die when dried, hence the process has a decided sanitary advantage. Further, dried fruits, vegetables or meats are rarely eaten raw, and the cooking is a further sanitary safeguard.

Drying has two principal advantages: (1) it reduces the weight and thereby simplifies the problem of handling and distribution; (2) it improves the keeping qualities of the food.

The effectiveness of drying as a food preservative depends upon the thoroughness with which the process is carried out. It is not so well adapted to meats as to vegetables and fruits. Dried meats lose their natural flavor, which may be replaced with others less real. All sorts of organic foodstuffs, even the most decomposable, such as milk, eggs, fruit, or meat, may be dried and, if kept dry, will keep in a satisfactory state almost without limit of time. Drying has little or no influence upon the vitamin content of foods. It certainly does not diminish the activity of "water-soluble B" which protects against beriberi. Dried leaves, such as celery tops and alfalfa are still good sources of "fat-soluble A," even when dried in the sun, or by artificial heat in a current of air after preliminary treatment with steam. Dried milk is also an efficient source of "fat-soluble A." On the other hand, drying may diminish the antiscorbutic value of food. Thus, dried milk loses about half its antiscorbutic properties.

Theoretically, dryness is not a complete safeguard, for the reason that a few microorganisms survive, particularly bacterial spores. Despite this slight limitation, it is more than reasonably safe and an entirely satisfactory procedure. Practically the only change in dried foods is the loss of moisture, which may readily again be supplied. Dryness has the great advantage in that no added chemical or added preservative process is necessary; further, dried foods are quite as nutritious and usually quite as digestible as the fresh articles, although not quite as savory.

*Dried Meat.*—In the dry climates of South America and on our western plains meat is cut into thin strips, suspended in the air, and exposed to direct sunlight. In a short time the moisture disappears and the hard, dry pieces keep indefinitely, or as long as they are kept dry. The meat retains a fair degree of palatability and practically all of its nutrient properties. This is known as jerked beef.

Dried beef is also prepared by first treating the meat with condiments and then drying it artificially. Chipped beef or dried beef is prepared in this manner, except that the meats are often smoked as well as salted and desiccated, so that in their method of preparation more than one method of preservation is employed.

Powdered meats are prepared by complete desiccation, and such products are found upon the market as a finely ground powder. Meat powders are made not alone from fresh meats in their natural state, but are also prepared after more or less artificial digestion.

*Dried Fruits.*—Dried apples are taken as a type of dried fruits and vegetables. The apples may be dried naturally by cutting them into convenient sizes and exposing them to the action of the sun. This is more a domestic than a commercial industry. When apples are dried by this simple process they darken and become unattractive in appearance. This is due to the oxidizing action of the enzymes when exposed to the air. When properly prepared the dried apple has its moisture content reduced to approximately 30 per cent. or less.

In order to prevent the darkening of the surface during the long exposure necessary to secure the proper degree of evaporation, apples are usually subjected to the fumes of burning sulphur. The sulphur dioxid acts as a bleaching agent and the sulphurous and sulphuric acids retained in the apple act as preservatives. Apples treated with sulphur fumes are less likely to decay or become infected with molds than a similar product not exposed to sulphur fumes. The process is objected to from the standpoint of health, for the reason that the sulphurous acids and sulphites are admittedly injurious to health. The Department of Agriculture found that approximately half of the evaporated fruits purchased on the open market had been treated with sulphur fumes. In order to obtain a satisfactory dried product it is of some importance that the fruits be selected, so as to reject all imperfect, rotten, or infected specimens.

*Evaporated apples* is a term applied to apples dried artificially instead of being exposed to the sun's heat. The process is rapid and satisfactory, and has no sanitary objections.

*Dried Eggs.*—Eggs are broken out, mixed and dried by spreading the mass in a thin film in shallow pans or upon a broad revolving belt; the water is abstracted by exposure to a current of warm, dry air. The egg substance may also be dried by forcing it through small orifices

under a high pressure into a drying chamber so adjusted as to temperature and size as to secure the desiccation of the minute particles of egg spray before they fall to the bottom. Egg substance thoroughly dried keeps satisfactorily in almost any climate. It retains all the nutritive value in the original egg.

**Dried Milk.**—Milk must be dried quickly in order that it will not spoil during the process, and the temperature must not be high enough to coagulate the lactalbumin, otherwise the addition of water would not restore the milk to its former homogeneous state. Milk may be dried in a very thin film on heated and revolving metal drums or on belts in a current of dry, warm air; or *in vacuo*. In this way the milk can be reduced to a dry state in a very short time and without reaching a temperature sufficiently high to produce physical changes. A favorite method of drying milk consists in atomizing it under pressure and projecting it into a warm chamber, the temperature of which is so regulated that the fine particles are completely deprived of their water before they reach the bottom of the cabinet. The milk is thus reduced almost at once to a fine powder. Dried milk when mixed with water is practically restored to its original condition. Milk powder should be either kept in a cool place or sealed in air-tight packages in order to prevent the fat becoming rancid. Dry, powdered milk properly cared for will keep almost indefinitely. Since practically 88 per cent. of milk is water, there is a decided economic gain, so far as the handling and transportation are concerned. Powdered milk should, of course, be made from milk derived from healthy cows handled under sanitary conditions and free from infection. The milk should be pasteurized before it is reduced to a powder. Powdered milk is finding an increasing and legitimate field of usefulness for cooking, household purposes, as a beverage for adults and even for infant feeding. It should, however, not be depended upon for infant feeding. Dried milk seems to retain all the qualities of the liquid product, except that it has lost some (about one-half) of its antiscorbutic properties.

**Salting and Pickling.**—The preservation of meat with brine or common salt is one of the oldest processes known. The brine should contain from 18 to 25 per cent. of salt. For red meats a little potassium nitrate is often added; this salt has slight antiseptic properties, but brings out the red color. Haldane has shown that nitrite is formed from the nitrate, and that some nitrous-oxidhemoglobin is formed, which gives a bright red color to the meat. In the processes of salting some of the meat protein, bases, and extractives are dissolved out and the fibers become hardened; the nutritive value and digestibility, therefore, are somewhat diminished. The brine should never be less than 6 per cent., for *B. botulinus* will not grow and produce its toxin in this concentration.

Pickling includes preservation of food in brine, vinegar, weak acids, and the like. These substances have antiseptic and also feeble germicidal properties, depending upon their concentration.

*Pickled meats* are prepared by soaking meat, especially pork, in a brine made of common salt, though other substances, such as sugar, vinegar, and spices, are often added. Chemical preservatives are sometimes added to the brine. Those most frequently used are sulphite of soda or boric acid. With proper methods these added chemical antiseptics are not necessary. The vinegar which is employed, or acetic acid, may be injected into the carcass before it is cut up. When the arteries are filled with vinegar in this way it rapidly permeates to all parts of the meat and acts as an excellent and unobjectionable preservative in cases where an acid taste is desired. It is stated that carcasses which have been injected with vinegar are easily preserved and require far less salt and other condimental substances than when not so treated. The process has no sanitary objections.

*Trichina* die after a prolonged period of pickling. *Cysticerci* die a natural death in 21 days following the death of the host. They are killed very promptly if placed in brine under conditions which will permit the rapid penetration of salt, but in practice, owing to variations in the rapidity of the penetration of salt into meat, this is not taken into consideration and pickled beef from affected cattle is considered free from viable *cysticerci* only after the expiration of three weeks following slaughter. Many pathogenic bacteria die in brine of this concentration, but the salt must be looked upon as an antiseptic rather than a germicide; that is, it prevents growth rather than kills the bacteria that are present. From a sanitary standpoint there is some, though slight, danger of conveying infection in foods that have been improperly salted or pickled. Attention is called to the fact that the first cases of botulism studied by van Ermengem were caused by ham kept in brine under conditions favoring anaërobic growth.

Decomposition may also be arrested by the use of syrups, which have an entirely similar action to that of salt, vinegar, or weak acids; that is, a strong solution of sugar will prevent growth, but cannot be depended upon to kill parasites. However, most pathogens die under such conditions in the course of time. As most preserved foodstuffs are cooked before eaten, there is small danger in articles prepared by these processes.

**Jellies and Preserves.**—By preserving is commonly understood the addition of a large amount of sugar. The principal preserves are jellies, marmalades, jams, and fruit butters. These substances are entirely free from the danger of conveying infection, not only on account of the antiseptic action of the sugar, but for the further reason that they are always cooked in preparation. Jellies are frequently adulter-

ated by the substitution of apple stock. Apples contain a large number of pectase bodies which favor jellification. Pectase bodies are carbohydrates ( $C_6H_{10}O_5$ )<sup>x</sup> similar in construction to cellulose. When pectase bodies are boiled with an acid, they are hydrolyzed to pectin bodies which take the jell form on cooling. If boiled too long, complete hydrolysis takes place and the pectin bodies are converted into glucose and glycosuric acid.

A common method of manufacturing jelly for the trade has been to use a stock of apple juice or cider, or a preparation made from the cores, skins, and rejected portions of the apple at evaporating factories, or from whole rejected apples. This stock is used as a common base for the manufacture of jellies of different kinds. Apple juice used as a substitute for other fruit juices in the making of preserves is a common fraud and an adulteration, according to the Food and Drugs Act, unless plainly stated upon the label. Phosphoric acids and other acids are added to jellies to enable jellification to take place with the use of less fruit and more water. Jellies are also adulterated with artificial coloring matter, particularly the coal-tar dyes. Artificial flavors which closely resemble the particular flavor desired are sometimes employed. The chemical preservatives most frequently added to jellies and preserved fruits are salicylic acid, benzoic acid, or benzoate of soda.

**Smoking.**—The smoking of fish, beef, hams, and other food products consist mainly in rapid drying plus the germicidal action of certain substances in the smoke.<sup>65</sup> The meat or fish is exposed to the smoke of a smoldering wood fire of oak, maple, or hickory, usually after a preliminary salting. The articles so exposed become dry and impregnated with pyroligneous products—acetic acid and creosote, formaldehyde, and other germicidal substances. The penetration is only partial.

An artificial or quick method of smoking meat is to brush the pieces or dip them in pyrolignic acid at definite intervals, and finally dry in the air. The effects of the smoking do not penetrate very far; therefore, in sausages of generous diameter putrefaction often occurs in the interior. Smoked sausage may, therefore, be dangerous, as far as various parasites and the products of decomposition are concerned, and the same is true of smoked ham and other meats exposed in large pieces. As smoked meats are often eaten raw, the occasional survival of parasites in such products has some sanitary significance.

**Canning.**—The process of canning is practically synonymous with sterilization and is, therefore, one of the best sanitary safeguards we have against parasites and the injurious products of putrefaction in foodstuffs. The process of canning was discovered by the confectioner,

<sup>65</sup> The process was probably accidentally discovered in connection with crude attempts to use artificial heat for drying purposes.

M. Appert, of Paris, in 1804-1809, long before the days of bacteriology.<sup>66</sup> Appert found that meats and other foods in sealed vessels would usually keep indefinitely if, after being sealed, they were kept for an hour in boiling water. He improved the process in 1810 by introducing a method of sealing the cans after the heating process had driven out the air and replaced it with steam, so that when cool a vacuum is formed. For all practical purposes this is the universal method of canning to-day.

In recent years, the method of fractional sterilization has been used especially in home canning processes. In this method the cans are given a second, and even a third heating after intervals of 24 hours, in order to permit the germination of spores.

Spoilage may result from insufficient processing, defective containers, or the use of unfit material. These losses are generally classed under the heads of *swells*, *flat sours*, and *leaks*. The ends of a swelled can bulge, and when opened there is evidence of gaseous fermentation and spoilage. "Flat sour" is a term applied to the acid decomposition without the formation of gas. "Leaks" are usually due to imperfect covers or to pin holes.

If we analyze the different factors responsible for the spoilage of canned fruits and vegetables, we will find that the most important are: (1) use of unfit raw material; (2) use of unfit cans and glass jars; (3) carelessness in the matter of cleanliness; (4) overfilling of the cans; (5) carelessness in sealing the cans; (6) imperfect methods of processing. No can that shows evidence of spoilage should be used as food.

Emphasis has always been placed upon the necessity of a vacuum for the proper preservation of canned foods. Bacteriologists, however, have shown that sterile foods may be kept indefinitely either in the presence or absence of air. *Sterility*, then, is the great desideratum, both from the sanitary and economic standpoints. The time and temperature of processing varies with the food and its condition as to freshness and cleanliness. Allowing foods to stand before processing permits resisting molds and spores to form and renders sterilization unnecessarily difficult.

There is also a prevalent notion that once opened, the contents of the can should be emptied into some other vessel. It is generally believed that food kept in an open tin can acquires injurious properties.

<sup>66</sup>Nicholas Appert, in France, first preserved food in glass jars by sealing them hermetically and heating, in 1804. He published "The Art of Preserving Animal and Vegetable Substances" in 1810. In 1810 Peter Durand obtained a patent in England for preserving fruits, vegetables and fish by hermetically sealing them in *tin* and glass cans. In 1820 William Underwood and Charles Mitchell, emigrant employees from a canning factory in England, opened a factory in Boston where they canned plums, quinces, cranberries and currants. Glass was used exclusively until 1825, when Thomas Kensett secured a patent for use of *tin* cans and commenced to use them in his factory.

This is a fable, like the souring of milk due to a thunderstorm. On the other hand, canned food may become contaminated or infected after opening, and the same care as to cleanliness and refrigeration is necessary as with fresh food or with cooked food.

The process of canning fortunately does not interfere seriously with most vitamins. It is now well known that these "unknown dietary factors" are for the most part not destroyed by heat in an acid medium; practically all our foodstuffs have an acid reaction. McCollum and Davis<sup>67</sup> have pointed out that wheat germ can be moistened and heated in an autoclave at fifteen pounds pressure for an hour or more without any extensive destruction of the "water-soluble B." and McCollum, Simmonds and Pitz<sup>68</sup> have subjected soaked navy beans to similar treatment without causing any great deterioration with respect to this dietary factor. This treatment is comparable to that to which fruits and vegetables are subjected when processed in canning, and shows that the widespread belief that canned foods have lost these dietary essentials is, at least, generally without foundation.<sup>69</sup> Hess has shown that canned tomatoes retain their antiscorbutic properties. Condensed and evaporated milk retain their "fat-soluble A" and antineuritic vitamins. The antiscorbutic vitamin is the most susceptible to heat and is injured or destroyed in many cooked or canned foods. (Effect of heat on vitamins, page 672.)

The objection is sometimes raised that the contents of the can are improperly sterilized and that the surviving spores germinate at the first opportunity and cause decomposition. Fortunately, an improperly sterilized can of food tells its own story, and the gaseous products of putrefaction may even burst the tin or leave the food in such condition that when the can is opened it would be so offensive to the sense of smell that no one would use it.

The process of canning fortunately does away with the necessity of using chemical preservatives of any kind. The proper authorities should be authorized to prohibit the canning of foodstuffs that have already undergone perceptible decomposition, or, if not injurious to health, they should be labeled "second quality." The law should require that the quantity contained within the can and the date on which it was put up as well as the amount should be stamped in the tin. This phase of the question is perhaps more of economic than of hygienic importance, but will be required in time as surely as the present law now requires honest labeling in other particulars.

Before meats are canned they are first parboiled for eight to twenty minutes, in order to secure the shrinkage before the meat is placed in

<sup>67</sup> *Journ. Biol. Chem.*, 1915, 247.

<sup>68</sup> *Ibid.*, 1917, 521.

<sup>69</sup> McCollum: "The Newer Knowledge of Nutrition," Macmillan Co., 1918.

the can. In the parboiling there is a certain loss of fat, soluble mineral matter, meat bases, and water. However, the shrinking of the meat concentrates it, as far as nutritive value is concerned, and, therefore, compensates for the loss. The parboiled meat is then placed in the tin and a small quantity of the soup liquor added. The cans are closed and then placed in autoclaves and subjected to steam under pressure. Usually a small hole is left in the can in order to permit the exit of air and gases. This is sealed off at once after heating. The cans are then subjected to a second heating at 225° to 250° F. from one to two hours. A modified process consists in placing the cans upon an endless conveyor which exposes the can to a high temperature in an oil bath a sufficient length of time to sterilize the contents at one exposure.

In Germany tuberculous and trichinous meat is sterilized and sold as second quality meat in accordance with the third class or "*freibank*" meat system. There is no known sanitary objection to this practice, provided the sterilization is complete and the label represents the true nature of the product. This practice has recently been recognized under our meat Inspection Service of the U. S. Bureau of Animal Industry.

Canned foods are sterile foods and, therefore, generally safe. Fresh foods, of course, are to be preferred to those that have been preserved, although many unsterilized foods are more dangerous in the fresh state than after they have been exposed to a high temperature. The process of canning has proved of inestimable benefit to mankind. It enables nourishing food of a perishable character to be kept and transported to great distances and to be used in localities where fresh foods are unobtainable. Without this method of preserving foods the pioneer and the explorer would be seriously handicapped. Large army and navy maneuvers would be materially impeded, and great metropolitan cities would be impossible. Wiley states that "the winning of the West has been marked by the *débris* of the rusty can."

Canned foods are not only safe, but are quite as nutritious as the original articles. The process permits us to have a well-balanced ration throughout the year—irrespective of season. The canning industry is growing to enormous proportions, and, on account of the great importance of the process, the character and quality of foods thus preserved should be wholly above suspicion, and no adulteration or sophistication of any kind permitted. Every can should be plainly stamped with the quantity and true nature of its contents and also the date when it was first sterilized.

Concerning the character of the container Wiley states: "Much in the direction of securing a better product may be accomplished by a more careful selection of the container. The common method of preserving canned goods is in tin. This material, as is well known, is placed

on the surface of sheet iron and should be free of other metals. Lead especially should be excluded from the composition of the tin as far as possible. In spite of all these precautions, however, the coating of the tin is sometimes broken, so that the iron itself may be attacked, perforations result, and the package of goods be spoiled. More frequently, however, the erosion of the tin plate occurs over widely extended areas, introducing into the contents of the package a considerable quantity of tin salts. This may be prevented to a certain degree by coating the surface of the tin with a gum or varnish which is not acted upon by the contents of the package. Glass is also coming into more general use, and if it could be secured of a character to avoid breakage it would be possible to replace to a considerable extent the tin packages now in such common use, and thus prevent the introduction of soluble tin salts into food. In this case the glass itself should be free of lead, borax, and fluorids."

Practically all foods canned in the ordinary way contain some tin. The amount varies with the acidity, and also the age and temperature of the package. Meat extracts, on account of their acidity, take up more tin than do most other meat products. For the same reason, certain fruits and vegetables, such as canned peaches, cherries, pears, apricots, pineapple, tomatoes, asparagus and tomato soup take up tin from the can. Canned lobster and shrimp are relatively active as solvents of tin on account of the amino-acids they contain.

Fortunately, tin is not very toxic. Cushny states that chronic poisoning from tin is unknown, and that animals present no symptoms when subjected to prolonged treatment with larger quantities of tin than are contained in any preserved foods. Schryver found no indications of cumulative action when as much as 2 grains per day is taken. There is a general agreement that tin plays no part of importance in connection with food poisoning, acute or chronic.

All told, canned foods are the safest foods that come to our table.

**Chemical Preservatives.**—Chemical preservatives are nothing more nor less than antiseptic substances; that is, substances which restrain the growth and development of bacteria and molds. Chemical preservatives in the proportions commonly used may have little or no germicidal action. Such substances as sugar, salt, vinegar, vinegar extract of spices, and the pyroligneous products in wood-smoke are not regarded as "chemical" preservatives, but as "natural" preservatives or condimental substances, although their mode of action is precisely the same as the chemical preservatives. There is a great prejudice against the use of any preservative for our foods if this preservative is a "chemical" or "drug," whereas no objection is raised to the same substance if derived from "natural" sources. Thus, foods exposed to a smoldering wood-fire become impregnated with pyroligneous acid, which includes creosote, acetic acid, and probably formaldehyd and other substances having anti-

septic properties. This method of food preservation is not only countenanced by the law, but is favored on account of the savory result and the antiquity of this "natural" process.

The great increase in the use of chemical preservatives in foods during the last fifty years is owing to the fact that this is the cheapest and surest method of preservation, thus offering a convenient method of supplying the needs of large communities as well as remote places. The question, however, has an economic side that cannot be disregarded. Here, however, we must confine ourselves to the health aspect of the problem. Fortunately we possess two efficient and wholly unobjectionable processes for the preservation of food, viz., refrigeration and sterilization by heat, which for the most part make it unnecessary to resort to the use of chemical preservatives. One of the most objectionable uses that can be made of chemical preservatives or any other method of food preservation is to conserve foods which are so decayed as to be unfit or possibly injurious to health if used fresh. The law cannot be too strictly enforced in order to prohibit the use of chemical preservatives and condiments used to disguise such foods, which may then be sold at high prices as first quality.

Upon general principles it is undesirable to add a chemical substance of whatever nature to food for the purpose of preserving, coloring, or improving its appearance, and in most countries this practice is prohibited by law. There are, however, a few instances in which the addition of some chemical preservatives in minimal amount seems harmless, and occasionally even desirable, as, for example, small quantities of benzoate of soda in catsup; a thin film of gum benzoin as a protective coating for chocolate, etc.

No sweeping generalization can be made concerning all chemical preservatives. Each substance must be considered for itself, and each substance must further be considered in relation to the particular foodstuff for which it is proposed. It may, however, be stated as a general rule that any chemical which is poisonous in large amounts should be considered as poisonous in small amounts until the contrary is proved. In other words, the consumer is entitled to the benefit of the doubt. The toxicology of various food preservatives is in its infancy and frequently presents a very difficult and complex problem. Thus, lead in one large dose is not particularly harmful. The older practitioners frequently gave twenty, thirty, and more grains of sugar of lead (acetate of lead) for diarrheal affections. Only a minute portion of the lead taken in one large dose is absorbed; the rest is quickly eliminated. However, if the same amount of lead should be taken in small subdivided daily doses, enough would be absorbed and retained by the tissues so that serious chronic lead intoxication would develop, resulting from the cumulative action. On the other hand, hydrocyanic acid, one of

the most poisonous chemicals known, is harmless in small amounts, for the reason that when introduced into the body it meets the available sulphur ( $\text{H}_2\text{S}$ ), with which it unites to form a sulphocyanid, as  $\text{KSCN}$ . The potassium sulphocyanid is not poisonous, and it has been shown experimentally that animals are able to withstand larger quantities of hydrocyanic acid by first giving them substances which increase the available amount of sulphur to form this chemical combination. Benzoic acid in large amounts is irritating and produces well-defined symptoms of poisoning; small amounts of benzoic acid are paired in the liver and eliminated by the kidneys as hippuric acid, a normal and harmless constituent of the urine. Hydrochloric acid, common salt, and possibly acetic acid and alcohol are all poisonous in large amounts, but they may be regarded as harmless if the amounts taken are sufficiently small. Even common salt in sufficient concentration is poisonous, and this affords a favorite method of suicide in China.

The point at issue now is to determine which of the chemical substances are injurious to health. In the present transitional state of our knowledge it is not possible to make a final statement concerning all or perhaps any one of them. It is well known that the most serious poisons may be taken in minute amounts without apparent injury. In fact, many medicinal substances in the pharmacopeia are very poisonous, but in therapeutic doses may be quite beneficial. The effect of the continued use of chemical substances in small amounts will require long and patient observation to determine whether or not they should be permitted as food preservatives. Of all the substances so far brought forward, the least harmful is benzoic acid and benzoate of soda. Hydrochloric acid, sodium chlorid, and possibly acetic acid, as well as benzoic acid and alcohol, are poisonous in large amounts, but seem to be harmless if the amounts taken are sufficiently small. There can, however, be no defense for the use of formaldehyd, salicylic acid, sulphites, and a host of other chemicals. So far as we know, the human organism possesses no natural mechanism for rendering them harmless.

There can be no defense for the use of chemical preservatives to hide inferiority. This is well illustrated in the case of bleached flour. The only purpose of the bleaching is to make the flour from a dark wheat look as white as the best patent flour. It was recently discovered that this "artificial aging" of flour may be accomplished by adding nitrogen peroxid. The flour absorbs this poisonous gas as a sponge absorbs water and instantly becomes white. Processes of this kind should be regarded as a common fraud, for the flour is not improved in any way except in appearance, which is, after all, a deception. The silly process of modifying the natural colors of food is illustrated in the use of copper sulphate to give peas a bright green hue, and the use of anilin dyes in glucose, jellies, fruit juices, ices, and other substances to imitate the

color of natural flavoring extracts. "Natural" colors, such as caramel and vegetable substances, are also frequently used. The substitution of cheap chemicals for high-priced natural flavoring extracts, the substitution of acetic acid or even mineral acids for genuine vinegar, the substitution of saccharin for sugar, the paraffin polishing of rice, and similar devices are nothing but common frauds, which may in some cases also be injurious to health.

*Benzoic Acid and Benzoate of Soda.*—Benzoic acid is an organic acid contained largely (12 to 20 per cent.) in gum benzoin, and also in balsam of Peru and balsam of Tolu. It is obtained from gum benzoin, from the urine of herbivorous animals, and artificially from toluene, by treating it with chlorin and heating with water to 150° C.

The storm center of the question of chemical preservatives in this country has raged about the use of sodium benzoate. Wiley conducted experiments upon a number of healthy individuals known as the "poison squad." These men were given rather large quantities of sodium benzoate with their meals and the result seemed to be an impairment of the appetite, disturbance of digestion, and other injurious effects in certain instances. On the other hand, the Referee Board appointed by President Roosevelt and consisting of Remsen, Chittenden, Long, Taylor, and Herter found that moderate quantities over a period of four months have no appreciable influence upon health.

The reason why benzoic acid in moderate amounts is believed to be harmless is that the body possesses a special mechanism for taking care of this substance. Many of our ordinary foods contain substances which are transformed in the body into benzoic acid. Some foods, such as cranberries, contain this acid in notable amounts. Benzoic acid meets glycocoll (one of the decomposition products of protein) in the liver. Benzoic acid and glycocoll form hippuric acid, a normal and harmless constituent of the urine. We know, therefore, that the human organism is prepared to take care of and render harmless a certain amount of benzoic acid; we know that this mechanism is a very efficient one and is capable of taking care of relatively large amounts of benzoic acid.

There can be no serious objection from the standpoint of health to the addition of 0.1 per cent. of sodium benzoate to catsup, on account of the small quantity of this article consumed at any one time. Further, on account of the long time a bottle of catsup is usually kept after it is opened in the household, there is, thus, the added economic gain of preserving the catsup until it is all consumed. The same object may be obtained by the use of a sufficiently strong vinegar extract of spices, but the question may be asked whether the aromatic and preserving substances in the vinegar extract of spices may not be more irritating than the sodium benzoate.

Hoffman and Evans<sup>70</sup> have shown that ginger, black pepper, and cayenne pepper fail to prevent the growth of microorganisms. Nutmeg and allspice have slight antiseptic properties, but only for a very few days. Cinnamon, cloves, and mustard, on the other hand, have very marked antiseptic powers and are valuable preservatives. The active antiseptic constituents of mustard, cinnamon, and cloves are the aromatic or essential oils which they contain.

No one would advocate the promiscuous use of sodium benzoate in foodstuffs generally. Its use in such foods as cider or tomato soup may be questioned on account of the amounts that would be taken in such articles. Further, benzoate of soda placed in an acid medium becomes benzoic acid. It is difficult to know where to draw the line, and the consumer must be given the benefit of the doubt, but the evidence seems fairly well established that in the case of benzoate of soda small amounts are harmless.

The question has a large economic significance in addition to its sanitary aspect, for it is claimed that benzoates as well as other chemical preservatives permit the use of rotten tomatoes, skins, and undesirable food which otherwise could not readily be preserved. Benzoate of soda is a rather feeble germicide at best, and in such dilute proportions as 0.1 per cent. has feeble antiseptic power.

*Borax and Boric Acid.*—Both boric acid and borax are only mild antiseptics. They are not very potent germicides. They are generally used together, for the reason that the combination of the two is more efficient than either one alone. Locally boric acid is not very irritating, and for this reason it has been extensively used in surgical practice. To some skins, however, it is very irritating, and cases are reported of its absorption from wounds and cavities when used too freely, causing depression and eruptions, such as erythema and urticaria. Fatal results have been reported in a few cases from injecting the solution into abscess sacs, or from washing out the stomach with it; or from taking a very large amount by mouth.<sup>71</sup>

Boric acid and borax are used for preserving meats, milk, butter, oysters, clams, fish, sausage, and other foods. For meat it is often mixed with salicylic acid and applied externally. For milk it was a common practice to add to one quart of milk 10 grains of a mixture of equal parts of borax and boric acid; for butter the amount used is about one-tenth of an ounce to the pound.

The effect of small amounts of boric acid and borax upon healthy human beings has been extensively studied and has resulted in conflicting testimony.

<sup>70</sup>*Journal of Industrial and Engineering Chemistry*, Nov., 1911, p. 835.

<sup>71</sup>*J. A. M. A.*, Feb. 5, 1921, LXXVI, p. 378.

On one hand we have the researches of Chittenden<sup>72</sup> and Liebreich<sup>73</sup> with dogs fed upon articles containing borax and boric acid. To say the least, in both series the digestion of the food was not notably impaired and the animals gained in weight. The same result followed the experiment made by Liebreich upon rabbits and guinea-pigs. No injury appears to have followed the administration of boric acid to pigs, calves, and children by the British Commission.<sup>74</sup> Tunnicliffe<sup>75</sup> made experiments from which he inferred that neither borax nor boric acid affected the health of the children experimented on. Vaughan and Veenboer<sup>76</sup> conclude that in the small amounts required for preserving cream and butter, and that used as an external dust on hams and bacon, both boric acid and borax are unobjectionable from a sanitary standpoint.

On the other hand, the experiments made by H. E. Annette<sup>77</sup> led him to an opposite conclusion. He found boric acid injurious to kittens, and naturally assumed that the use of milk containing it might be hurtful to young infants. Foster and Schlenker<sup>78</sup> found that albumin digestion was impaired by boric acid, which also produced increased desquamation of the intestinal epithelium. Doane and Price<sup>79</sup> made experiments on calves which indicate that borax and boric acid in milk retard digestion to a slight extent.

As these substances are not normal constituents of the body, nor are they normal constituents of foods, the conservative course would be to avoid their use until satisfactory evidence has been adduced that they are free from harm in the amounts commonly used for preserving food.

*Formaldehyd.*—Formaldehyd has been and still is used extensively as a preservative for milk and other articles of food. Concentrated solutions of formaldehyd in large quantities is irritating, and death in isolated instances has been reported from the swallowing of amounts of from 1 to 3 ounces. There has been much discussion as to the effect of the small quantities ordinarily used as a food preservative. Bliss and Novy<sup>80</sup> and Halliburton<sup>81</sup> have shown conclusively that small quantities of formaldehyd greatly delay the digestion of proteins by the gastric and pancreatic juices, the digestion of starch by the pancreatic juice, and the curdling of milk by rennet. It is also known that some individuals are especially susceptible to the effect of formalin, small quantities in the

food causing dyspepsia and other disturbances of digestion. Formaldehyd unites directly with protein matter to form new compounds of an undetermined nature. Thus, formaldehyd added to egg albumin prevents its coagulation by heat, and added to gelatin prevents liquefaction. It hardens tissues, so that it will render fish and meat tough and brittle, even in proportions as dilute as 1 to 5,000, hence it is not generally applicable as a food preservative. In small amounts it delays decomposition; in large amounts it is an active germicide. Its use in milk was recently advocated by no less an authority than von Behring, but this view met with almost unanimous protest.

There can be only one opinion concerning the use of formaldehyd in foods, and that is absolute condemnation of the practice. It is prohibited by the statutes of practically all nations having pure food laws.

*Salicylic Acid.*—Individuals differ greatly in their susceptibility to salicylic acid. In mild cases of poisoning with this substance there is a feeling of fullness in the head with roaring sounds in the ears, dimness of vision, profuse perspiration, confusion, and dullness. Large doses of the acid cause intense irritation of the throat and stomach, leading to vomiting and difficulty in swallowing. Later there may be diarrhea. Eczema and other skin eruptions may appear, and dimness of vision and deafness may continue for some time. The long-continued use of salicylic acid and its salts has led to a form of chronic poisoning in which the chief symptoms have been loss of appetite, diarrhea alternating with constipation, irritation of the kidneys, skin eruptions, and mental depression. Such results are said to have followed the use of articles of diet preserved with salicylic acid. The use of such foods may be objectionable in the case of aged, feeble, and susceptible persons. Salicylic acid and the salicylates are more efficient antiseptics than boric acid or borax, but they are not used extensively on account of the taste, or rather the tendency to cause unpleasant flavors. They are for the most part used in jams, fruit juices, soda water syrups, cider, wines, and other sweet preparations. The objection to the use of salicylic acid in food is practically unanimous and well founded.

*Sodium Nitrate.*—Sodium nitrate or potassium nitrate (saltpeter) is not used as a preservative, but as an indirect coloring matter. It retains and accentuates the red color of meat. It is not known to be harmful in the small quantities in which it is commonly employed, but must be regarded as a fraud when used to make stale meat look fresh.

*Potassium Permanganate* is also used on the surface of meat to destroy the surface evidence of decomposition. This may be detected by heating a knife in hot water, plunging it into the meat, and withdrawing it quickly. This brings out the hidden odors of putrefactive changes.

*Sodium Fluorid.*—Sodium fluorid has been extensively used as a preservative, antiseptic, and insecticide. It has considerable antiseptic power, putrefaction being delayed by the addition of 1 part to 500; and 1 in 200 arrests completely the growth of bacteria. It is highly poisonous to nearly all the lower forms of life, especially to microörganisms, including algae. It does not coagulate protoplasm but acts as a general protoplasmic poison. For mammals, sodium fluorid is not a very toxic substance, the fatal dose by the mouth being 0.5 gram per kilogram of body weight, and subcutaneously 0.15 gram per kilogram of body weight. The fluorids on administration are deposited in the bones, which usually become white and brittle, and contain crystals of calcium fluorid. It is well to call attention to the fact that fluorin, in very small traces, is a normal constituent of bone, teeth, milk, eggs, etc. In large amounts and concentrated, it is directly irritating to the mucous membrane and produces vomiting, diarrhea, and abdominal pains. Death of a ten-year-old girl has been caused by the ingestion of one teaspoonful in a little water, given in mistake for Rochelle salt.<sup>82</sup> Baldwin<sup>83</sup> reports a number of cases of sickness and death resulting from the accidental ingestion of sodium fluorid, usually taken in mistake for baking powder. Recovery from non-fatal doses is usually rapid and complete. There is no evidence that small quantities ingested daily for a long period of time are harmful.

Sodium fluorid forms the basis of most roach powders which contain from 16 to 47 per cent. of the fluorid finely ground up and intimately mixed with the bait. It is fatal to roaches when so ingested.

*Hydrofluoric Acid.*—Schultz<sup>84</sup> exposed cats for four days to concentrated fumes of hydrofluoric acid without serious effects. The air was so impregnated that glass held at some distance from the source was etched. Hydrofluoric acid is much used in breweries for disinfecting vats and tanks. It is a powerful germicide.

*Sulphites.*—Sulphites act as antiseptics and also preserve the red color of meats. Sodium sulphite and bisulphite and sulphurous acid are used principally upon fresh meats, where they act as a preservative and as a retainer of color. Sulphur dioxid is also much employed for the bleaching of fruits. Sulphites, even in minute amounts, interfere with the action of ferments, and thus influence digestion. Free sulphurous acid is very irritating. Sodium sulphite is very poisonous when injected subcutaneously or intravenously. Death occurs by paralysis of respiration. Much larger quantities are tolerated by the mouth, the sulphite being slowly absorbed. The greater part is converted to the harmless sulphate during and after absorption. The quantities ordinarily used in preserved food cause no immediate symptoms, even when con-

<sup>84</sup> Schultz, K.: *Arch. f. Exp. Path.*, 1889.

tinued for several months. If, however, the animals are killed and examined, extensive hemorrhagic and inflammatory lesions are found in various organs.<sup>85</sup> These lesions are probably due to destruction of red blood cells or infarction. Harrington in 1904 also described nephritic changes. In 1898 the Imperial Board of Health in Germany forbade the use of sodium sulphite in food on account of its dangerous properties, and it is also forbidden by our Federal Pure Food Act of 1906.

*Sodium Bicarbonate.*—Sodium bicarbonate is too ineffective as a germicide for general use as a food preservative. It is sometimes added to milk in order to neutralize the excess of acid.

*Hydrogen Peroxid.*—Hydrogen peroxid is perhaps one of the least dangerous of the chemical preservatives, and is considered by some to exert no deleterious effect whatever in the quantities commonly used. It is used for the preservation of wine, beer, and fruit juices, and also in milk.

*Arsenic.*—Arsenic in food comes from a variety of sources. Glucose is apt to contain it, especially if impure acid is used to hydrolyze starch in the production of glucose. This was the source of the arsenic in the beer which caused the epidemic of peripheral neuritis in 1900 in England. Samples of the glucose contained from 0.01 to 0.1 per cent. of arsenic. The finished beer contained from 1 to 3 grains of arsenic per gallon. Arsenic may also contaminate certain anilin dyes as well as shellac,<sup>86</sup> which is now so much used as a coating for some kinds of cheap confectionery and bakers' goods, and also as a varnish on receptacles and containers of various kinds. Another source of arsenic in food is from insecticide sprays (page 279).

In England liquid food is considered adulterated if it contains as much as 0.01 grain of arsenic per gallon, and solid foods are considered deleterious if they contain as much as 0.01 grain per pound.

The use of preservatives containing lead, arsenic, or other substances known to be poisonous finds no advocates.

## THE PREPARATION OF FOOD

**Cooking.**—Cooking may be regarded as the greatest sanitary innovation ever introduced by man to protect himself against infection. The heat required for thorough cooking kills most microorganisms pathogenic for man and, therefore, renders food safe, so far as these dangers are concerned. The heat also kills the true bacterial toxins, which are destroyed in a few minutes at 70° C. Foods may sometimes contain heat-resisting poisons. Thus, boiling has no effect upon muscarin, a

<sup>85</sup> Kionka and Ebstein, 1902.

<sup>86</sup> Smith, B. H.: "The Arsenic Content of Shellac and the Contamination of Foods from This Source," *Cir. 91*, U. S. Dept. Agr., Bureau of Chemistry, Washington, 1912.

poison in certain toadstools. Heat also does not destroy a principle sometimes found in poisonous mussels. The colon bacillus and other microorganisms produce thermostable substances that are poisonous when injected into the lower animals, but the relation of these heat-resisting toxic substances to food poisoning in man is conjectural. It is highly improbable that foods contain heat-resisting poisons resulting from bacterial decomposition that are injurious when taken by the mouth.

Trichinae, according to some authorities, die at 65° C., but the Bureau of Animal Industry after repeated experiments places the thermal death point at a temperature of 55° C.; some writers state that cysticerci, or the larval stage of tapeworms, die at 52° C.; the non-sporulating bacteria are for the most part destroyed at 60° C. Food thoroughly cooked throughout will always reach these temperatures, but much meat and many vegetable food substances are preferred rare or underdone, and, while the outside of a large piece of meat may be thoroughly cooked or even charred, the interior may be practically raw or at least not have reached the temperature necessary to destroy parasites. A dish of spaghetti, charred on the outside, may not kill typhoid bacilli in the center of the mass (page 115).

Meat that is well cooked throughout always reaches from 60°-70° C. on the inside. It should be remembered that heat penetrates a large piece of meat slowly. For example, it requires 1½ hours in boiling water for the temperature to reach 62° C. in the interior of a piece of meat weighing 3½ pounds. Meat placed in a quick oven or broiled soon forms a hard, coagulated and insulated coating that retains the juices, but retards the penetration of the heat. See also page 695.

Cooking softens the connective tissue and renders meat more tender. The bundles of fibrillae are loosened from each other, the albumin is coagulated, the flavors are improved, and new flavors are developed, all of which enhance its digestibility.

Metchnikoff in his "new" hygiene dwells upon the great sanitary value of cooking. Perhaps no other single factor in preventive medicine protects us to an equal degree against infection. Metchnikoff believes that we should eat nothing in its raw state. This seem almost as extreme as the cult which proclaims the contrary. If for any reason cooking were to cease, there would be such a great increase of infections as to amount to a calamity.

One of the important functions in the preparation of food is to render it savory, tender, and appetizing. Foods that appear inviting aid digestion by stimulating the secretion and flow of the digestive juices. Foods that are rendered soft and tender are more readily digested, but it should not be forgotten that the teeth need exercise to keep them in good condition. Tough meats may be pounded to separate the connective tissue bundles, or may be chopped or minced as an arti-

ficial aid to mastication,\*or may be steeped for several hours in fresh milk or sour milk, in which case the fibers are softened through the action of the bacteria and their enzymes. In the case of vegetables, cooking breaks open and softens the cellulose envelopes and fibers; the starch grains swell and burst, and the insoluble starch is converted into soluble starch or dextrin.

Cooking has a few minor disadvantages—there is a loss of mineral salts, and some of the nutritive constituents, also a diminution in the antiscorbutic property of food generally.

Fermentation is of great use in the preparation of foods. The best example is the leavening of bread. The yeast ferments the carbohydrates in the flour with the production of carbon dioxide and alcohol. The carbon dioxide renders the bread porous; the gas is held within the loaf on account of the glutinous property of the protein (gluten) in the flour. Fermentation is an adjunct in the preparation of many other foods and beverages, such as cheese, sauerkraut, vinegar, beer, wine, cider, etc.

The observations of Becker, Grove, and others concerning the heat of cooking are practical and important in the preparation of food. Exposure to moist heat at 60° to 70° C. for a long time has the advantage of cooking foods thoroughly throughout. This treatment prevents burning or the results of overheating; the juices are retained. The process requires little or no attention. Meat is thereby rendered tender and juicy, vegetables thoroughly soft, and the starch grains are all opened. A modification of this method is found in the fireless cookers now offered for sale in various forms. These devices consist simply of a well-insulated box. The food is first heated, then placed in suitable compartments, and a temperature above 70° C. maintained for many hours.

Certain precautions are advisable in the choice of pots and pans used in cooking. Brass and copper are not advisable, and if used must be kept scrupulously clean. Copper acetate (verdigris) which sometimes forms in copper food containers, is greatly feared but is not very toxic. Acid foods should not be cooked in copper vessels, and milk and saccharin substances should not be kept in copper containers on account of the possibility of the organic acids dissolving the copper. Tin, nickel, and aluminum ware are least objectionable. Enameled ware is entirely satisfactory, provided it does not contain lead.

**Methods of Cooking.**—Much depends upon the method of cooking. The principal methods in ordinary use are: roasting, broiling, boiling, frying, and stewing.

*Roasting or broiling* causes considerable shrinking, due mainly to loss of water. The heat coagulates the exterior of the meat and thus prevents the further loss of juices and drying up. In order to obtain adequate heating of the meat throughout a large joint without burning

and drying the exterior, it is necessary to baste it from time to time with hot melted fat. This also helps to form a protective coating.

*In boiling* the meat is placed either in hot or cold water, depending upon the object desired. If it is desired to maintain the flavors within the mass, the meat should be plunged into boiling water. This quickly coagulates the albumins at the surface. If a rich broth is desired the meat should be placed in cold water and gradually heated. In this way the soluble proteins and extractives pass out into the surrounding water. The albumin of meat begins to coagulate at 134° F. (56° C.); the connective tissue is changed to gelatin and dissolved above 160° F. (72° C.). Long boiling makes meat fibers tough.

*Frying* consists in placing meat or other substances into very hot fat, lard, or vegetable oil. This causes a speedy coagulation of the surface similar in all respects to that brought about in the first mentioned process of boiling. The flavors and juices are thereby retained. If the fat is not very hot it will penetrate the tissues and cause the meat or other substance to become greasy and unpalatable. Fried substances are apt to be indigestible on account of the large amount of grease that adheres to and penetrates into them. It is, therefore, better to plunge food into deep fat, piping hot.

*In stewing* the meat is cut into small pieces and placed in cold water, which then is heated slowly to about 180° F. (84° C.), at which the whole is kept for several hours. If heated above 180° F. the meat becomes tough, stringy, unpalatable, and of diminished digestibility.

## CHAPTER II

### ANIMAL FOODS: MILK

The animal foods used by man are not of great variety and source. They include the flesh and various organs of the herbivorous animals, swine, domestic and wild fowl, eggs, fish, shellfish, insects and their products (honey), milk, and milk products. The flesh of carnivorous animals, except that of fish, is unpalatable and, therefore, undesirable as a food.

The most important animal foods from the standpoint of the sanitarian are milk and meat.

### MILK

Milk is our most important food. It is the best single food. The exceptional value of milk is due to the fact that it contains all the essentials of a balanced diet; it is rich in vitamins, the quality of its protein is especially high, the fat favors growth, and it has a high calcium content in readily usable form. Milk, furthermore, is palatable, readily digestible, and is subject to a great variety of modifications. Even at present prices, it is one of the cheapest of the standard articles of diet, and the most economical source of protein. Milk is a protective food, in that it guards against deficiency diseases when used in combination with other foodstuffs of either animal or vegetable origin.

"Those peoples who have employed the leaf of the plant as their sole protective food are characterized by small stature, relatively short span of life, high infant mortality, and by contended adherence to the employment of the simple mechanical inventions of their forefathers. The peoples who have made liberal use of milk as a food, have, in contrast, attained greater size, greater longevity, and have been much more successful in the rearing of their young. They have been more aggressive than the non-milk using peoples, and have achieved much greater advancement in literature, science and art. They have developed in a higher degree educational and political systems which offer the greatest opportunity for the individual to develop his powers. Such development has a physiological basis, and there seems every reason to believe that it is fundamentally related to nutrition."<sup>1</sup> (McCollum.)

<sup>1</sup> "The Newer Knowledge of Nutrition," The Macmillan Co., 1918.

The sanitarian therefore has every reason to encourage the use of milk, and to insist upon the supply being fresh, clean and safe. Children should drink a quart of milk a day, adults a pint.

The total milk production in the United States in 1919 was ten billion gallons. One-quarter of this is consumed as milk and the remaining three-quarters is used for butter and cheese. The average per capita consumption of milk in the United States is about 0.6 of a pint daily. More milk is used in the North than in the South; very little in the tropics, and practically none at all in China, Japan, and some other countries. About 16 per cent. of the average dietary in the United States consists of milk and milk products.

Milk has certain disadvantages that must be taken into account. As the sole article of diet for adults, it lacks iron<sup>2</sup> and roughage; it tends to produce constipation and because of its high protein content may lead to putrefactive changes in the intestines.

Milk is probably responsible for more sickness and deaths than perhaps all other foods combined. There are several reasons for this: (1) Milk conveys a greater variety of infections than any other food. Bacteria grow well in milk; therefore, a very slight infection may produce widespread and serious results; (2) of all foodstuffs milk is the most difficult to obtain, handle, transport, and deliver in a clean, fresh, and satisfactory condition; (3) it is the most readily decomposable of all our foods; (4) finally, milk is the only standard article of diet obtained from animal sources consumed in its raw state.

Fresh milk products may be quite as dangerous as the milk from which they are made. Milk laws which ignore milk products are incomplete from the sanitary side, and will fail to accomplish their purpose from the economic side.

Milk is a perfect food for the suckling. It is the best single food to promote growth and nutrition in growing children. It contains all the essential elements of a well balanced diet for the adult. As a sole article of diet, it lacks iron and roughage. At prevailing prices it is one of the cheapest of the standard articles of diet. Furthermore, it is readily digestible, and is capable of a great variety of modifications. The sanitarian therefore has every reason to encourage the use of pure milk, as well as to discourage the use of poor milk.

**Composition.**—Milk is the secretion of the mammary gland. In composition it is exceedingly complex, consisting chiefly of water; several proteins in colloidal suspension; fats in emulsion; sugar, and a number of inorganic salts in solution; also vitamins, phosphatids, enzymes, as

<sup>2</sup> Milk is deficient in iron. It has long been known that there is deposited in the spleen of the new-born animal a reserve supply of iron, which ordinarily suffices to tide it over the suckling period. Ordinary drinking water almost always contains small amounts of iron, and this doubtless aids in some degree in preventing iron starvation in the infant.

well as antibodies, cells, gases, and other substances. Milk from all species of animals shows a general agreement in physical properties and composition, containing essentially the same ingredients, but exhibiting differences in the relative amounts of the several constituents.

In the fresh state milk is a yellowish white, opaque fluid. Cow's milk has a specific gravity of 1.027 to 1.035; it freezes at a temperature somewhat lower than the freezing point of water ( $-0.554^{\circ}\text{C}.$ ); the electrical conductivity is  $43.8 \times 10^{-4}$  for cow's milk, and  $22.6 \times 10^{-4}$  for human milk. In other words, 58 per cent. of the molecules in cow's milk and 26 per cent. in human milk are dissociated. The specific heat of milk containing 3.17 per cent. of fat is 0.9457. The coefficient of expansion is greater than that of water. Milk shows no maximum of density above  $1^{\circ}\text{C}.$

Freshly drawn milk of carnivorous animals is, as a rule, acid in reaction. This is probably due to  $\text{CO}_2$  and acid phosphates. Human milk and that of most of the herbivora are slightly alkaline; cow's milk has been described as amphoteric. Fresh cow's milk is slightly acid to phenolphthalein; but strongly alkaline to methyl orange, indicating that the acidity is due in part to the acid phosphates. The pH values of fresh cow's milk range between 6.50 and 6.8; fresh mother's milk varies between 7.1 and 7.6.

Under the microscope milk is found to contain fat globules and cells, as well as bacteria, debris, and other objects.

The gases dissolved in milk<sup>3</sup> are oxygen, nitrogen, and carbon dioxide (3 to 4 per cent. by volume). Oxygen and nitrogen are carried into milk mechanically from the air in the process of milking. Other substances found in milk, but in small quantities, are lecithin, cholesterolin, citric acid, lactosin, orotic acid, and ammonia.

The composition of cow's milk may be understood from the schemes prepared by Lucius L. Van Slyke and S. M. Babcock, given on page 757.

Van Slyke and Bosworth<sup>4</sup> suggest the following as representing the principal constituents of milk more closely than previous statements. The amounts are based on milk of average composition:

	<i>Per Cent.</i>
Fat .....	3.90
Milk sugar .....	4.90
Proteins combined with calcium .....	3.20
Dicalcium phosphate ( $\text{CaHPO}_4$ ) .....	0.175
Calcium chlorid ( $\text{CaCl}_2$ ) .....	0.119
Monomagnesium phosphate ( $\text{MgH}_2\text{P}_2\text{O}_7$ ) .....	0.103
Sodium citrate ( $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7$ ) .....	0.222
Potassium citrate ( $\text{K}_3\text{C}_6\text{H}_5\text{O}_7$ ) .....	0.052
Dipotassium phosphate ( $\text{K}_2\text{HPO}_4$ ) .....	0.230
Total solids .....	12.901

<sup>3</sup> When not otherwise specified in this section milk refers to cow's milk.

<sup>4</sup> *Jour. Biol. Chem.*, XX, 2, Feb., 1915.

Milk is the best source of calcium in the dietary, both on account of the quantity and the usable form in which it exists.

*Proteins.*—The three proteins constantly found in milk are casein, lactalbumin, and lactoglobulin. A trace of fibrin, mucin, and other proteins sometimes occurs.

The proteins in milk of a given species are quite constant both in composition and amount; it is, therefore, not necessary, as a rule, to make a special analysis for them. They may be estimated by subtracting the fat, sugar, and ash from the total solids.

*Casein* is a highly specialized protein found in the secretion of the milk glands of all mammals, but nowhere else in nature; it is a nuclealbumin, and as such contains phosphorus. Casein is a complete protein—that is, it contains all of the 17 or 18 amino-acids necessary to rebuild human protein. It is insoluble in water, but by virtue of its property as an acid it forms soluble salts with alkalis. There are two series of casein salts, basic and neutral; solutions of the latter have a milky appearance. In milk, casein is found dissolved in the form of a neutral calcium salt, which accounts in part for the white opalescent appearance of milk. Casein really exists in milk in the form of *caseinogen*, that is, casein in combination with calcium phosphate. The caseinogen is held in solution by the calcium phosphate. It is not coagulated by heat, but is precipitated by acids, for the reason that acids take the calcium from the calcium phosphate, and thus throw the casein out of solution as a curd. This flaky or lumpy precipitate is again soluble in limewater and dilute alkalis. Casein is also precipitated by rennin.

*Lactalbumin* is very similar to the serum albumin of the blood, but it appears to differ from this in some particulars. It coagulates by heating to 70° C., but not with dilute acids, and is precipitated by a saturated solution of ammonium sulphate, but, like all other albumins, is not precipitated in a neutral solution of sodium chlorid and magnesium sulphate. Lactalbumin contains sulphur but no phosphorus. It is present in amounts varying from 0.2 to 0.8 per cent., but is much more abundant in colostrum.

*Lactoglobulin* occurs in milk merely in traces, while colostrum is comparatively rich in this protein. It coagulates at 75° C., it is precipitated in the same way as serum-globulin, and, like serum-globulin, is insoluble in water, but is soluble to some extent in weak salt solution.

*Fat.*—The fat is suspended in the milk serum in the form of an emulsion. The droplets or globules vary in size. On the average they are smaller in milk from Holstein than from Jersey, Guernsey, or short-horned breeds. Under the microscope some of the fat globules seem to have an albuminous membrane, but this interpretation is questioned. The fat droplets are lighter than the milk serum, therefore they rise

on standing (gravity cream), or else they may readily be separated by centrifugal force (centrifugal cream). Cream, or top milk, does not consist of fat alone, but contains all the constituents of the milk; it is simply milk rich in fat. Upon shaking the fat globules gradually coalesce into larger drops and lumps to form butter.

The first milk drawn from the udder is commonly poor in fat. This is known as "fore" milk. The middle portion contains about the average percentage, and the last, known as "strippings," is always the richest in fat. The strippings may contain as much as 9 or 10 per cent.

Heat increases the viscosity of milk, and hence hinders the rising of the fat drops; 68° C. is the critical temperature; if heated above this point for any length of time the formation of the cream line is retarded or prevented. For this and other reasons the richness of milk, therefore, cannot always be judged by the depth of the cream layer.

Milk fat consists of a mixture of different neutral fats, the principal of which are olein, palmitin, and stearin. These are neutral triglycerids of the corresponding fatty acids. Besides these are found the triglycerids of myristic, butyric, and caprylic acids. The last two are volatile and give to butter its characteristic odor and flavor. Crowther and Hynd<sup>5</sup> state that the only acids present in more than minimal proportions are the unsaturated acid, oleic acid, and the eight saturated acids of the acetic series ( $C_4$  to  $C_{18}$ ), namely, butyric, caproic, caprylic, capric, lauric, myristic, palmitic and stearic acids. The composition of the fat is subject to variation, depending upon racial or individual peculiarities, also upon the character of the food and other conditions.

Milk fat is rich in "fat-soluble A." This vitamin promotes growth; its absence induces xerophthalmia and serious disturbances of nutrition. Osborne and Mendel<sup>5</sup> have shown that butter fat may have a blast of steam passed through it for two hours and still retain its peculiar growth-promoting properties. This observation is in harmony with those of McCollum and Davis, that heating butter fat to the temperature of boiling water does not affect its peculiar dietary value. It is apparent, therefore, that any conditions to which milk fats are liable to be subjected during the cooking of foods will not greatly alter its value as a source of "fat-soluble A." Evaporated and dried milk also retains the virtues of this vitamin.

It is now clear that milk fat has no superior in dietetic or nutritional value.

The percentage of butter fat in milk has long been one of the standards by which milk is tested. The richness of milk gauged by the amount of fat it contains is more of an economic than a sanitary question. Milk with a lower percentage of fat from Holstein cows is relatively just as nutritious a food as richer milk from Jersey and Guern-

<sup>5</sup> *Biochem. Journ.*, 1917, II, 139.

sey cows; even skimmed milk containing little or no fat is a valuable food. The problem is one of honest labeling and the marketing of various grades at prices corresponding to their nutritive contents. When the standard for butter fat in milk is relatively low, say 3.25 per cent., it is a temptation for dairy men to standardize or adjust. A high fat standard encourages the breeding of better cows; requires caution in their feeding and care, and puts a premium upon good dairy methods.

In normal milk the larger proportion of fat droplets agglutinate into tiny clusters or masses. At a temperature of 65° C. or above these clusters are broken up and the globules are more homogeneously distributed throughout the liquid. When milk is sprayed or atomized at a pressure of about 3,000 pounds at a temperature of about 75° C. the individual fat globules are broken up into fine particles, which remain as a uniform and permanent emulsion known as "homogenized milk." This process applied to cream increases its volume and viscosity, so that cream containing 20 per cent. butter fat appears to have the body and richness of a 30 per cent. cream.

Researches of Heubner, Keller, and Czerny show that the fats and not the proteins are the cause of much of the digestive disturbances in infants. When the fat is excessive in amount the infant at first seems to thrive, but sooner or later loses weight and appetite, and shows other symptoms, associated with stools composed largely of fat soaps and of a pale gray, hard, and dry constituency. The alkaline bases are so largely drawn upon from the body to saponify the excessive amount of fat in the intestines, that a condition resembling acidosis may appear; furthermore, fermentative changes take place in the intestines and the "catastrophe" ensues.

Fat is the most variable constituent in milk. The amount varies with different animals, and even in the same animal from time to time.

*Milk Sugar, or Lactose.*—Milk sugar, or lactose ( $C_{12}H_{22}O_{11}$ ), is peculiar to milk; it is found nowhere else in nature. Commercially, milk sugar is obtained from whey as hard rhombic crystals, which have a slightly sweet taste and are soluble in six parts of cold water. Lactose is readily acted upon by microorganisms and reduced to glucose and galactose; the glucose is further changed to lactic acid. This is the common cause of sour milk (see *The Fermentation of Milk*, page 769).

Lactose, like glucose, reduces Fehling's solution when heated; it is dextrorotary. When heated above the boiling point of water it changes to a brownish color as a result of the formation of lactocaramel.

The amount of lactose in milk of any given species is remarkably constant.

*Vitamins.*—Milk is rich in "fat-soluble A," "water-soluble B," and fresh milk has a moderate antiscorbutic property ("water-soluble C"). The first two resist heating, drying, and age, but the last named deteri-

orates in time, and is injured by heat and drying. It is therefore essential to give orange juice or other antiscorbutic to infants fed on cow's milk, especially if stale, heated or dried. See also page 685.

**Ferments or "Life" in Milk.**—Milk contains a large number of very active ferments or enzymes. These substances are the nearest approach to "life" that we know of in milk. Milk also possesses certain other properties common to blood and living tissues, but, while milk may properly be regarded as a vital fluid, it possesses none of the fundamental properties of life. In fact, milk begins to decay the moment it is drawn; oftentimes decomposition begins while the milk is still within the udder. It would, therefore, be more proper to regard milk as a dead fluid, in the same sense that shed blood is dead.

The ferments are believed to be important to the infant, and this importance has been emphasized especially since the introduction of pasteurization, for the reason that a high degree of heat destroys them. Some of the ferments in milk are normal constituents of that secretion, while others are produced by bacteria. Many tests have been devised to determine the kinds and activity of the ferments in milk. The tests most frequently and successfully used are those for catalases and reductases. The absence of certain ferments in milk indicates that it has been heated. The presence of certain ferments gives an indication of the age of the milk, and the number of bacteria it contains, and also helps to distinguish between fresh normal milk and pathologically changed milk. See Tests for Enzymes, page 808.

The enzymes in milk are the following:

**Galactase.**—Galactase is a proteolytic ferment, similar to trypsin. It was found by Babcock and Russell to be abundant in separator slime. Ordinarily galactase by itself acts too slowly to cause any material change in the proteins in the short intervals which elapse between the withdrawal of the milk from the animal and its consumption as food. Snyder claims that this enzyme probably assists digestion, in that when milk is used in a mixed diet the proteins have been found to be from 4 to 5 per cent. more digestible than when milk is omitted from the diet.

**Lactokinase.**—Hougardy has shown that milk contains a ferment or a kinase similar to enterokinase. Lactokinase has been found to accelerate the digestion of proteins by pancreatic juice. This property is destroyed by heating the milk at 73° to 75° C.

**Lipase.**—This fat-splitting ferment was found in milk by Marfan and Gillet. Human milk exhibits this property to a higher degree than cow's milk. The former has a lipolytic activity of from 20 to 30 on Harriot's scale, while cow's milk shows an activity of only 6 to 8. Lipase withstands cold, but is destroyed by heating to 65° C.; it is non-

dialyzable and is held back by a porcelain filter. It probably hydrolyzes the higher fats of milk, at least to some extent, and may possibly account for a small part of the acidity of some milk.

*Catalase*.—Milk contains no true oxidases or oxidizing ferments proper (Kastle). It decomposes hydrogen peroxid and has the power of effecting the oxidation of a considerable number of easily oxidizable substances in the presence of hydrogen peroxid or ozonized oil of turpentine. In other words, milk contains catalase and peroxidase. Catalase is widely distributed among animals and plants; in milk it is probably of bacterial origin. Jolles has pointed out that human milk decomposes five or six times as much hydrogen peroxid as cow's milk. Considerable importance has been attached to this difference, which has also been used to distinguish human milk from cow's milk. Little is known of the function of catalase. Hydrogen peroxid is probably formed in both animal and vegetable tissues during vital activities. The catalase would destroy it and thus prevent its accumulation in the cell, which otherwise would destroy its life.

*Peroxidase*.—Milk contains substances capable of inducing the oxidation of guaiacum and other readily oxidizable substances by means of hydrogen peroxid or ozonized oil of turpentine. These substances are known as peroxidases. The peroxidases are destroyed when milk is heated to 80° C. The color reactions for these ferments are a convenient test to determine whether milk has been heated beyond a certain temperature or not. The interpretation of this reaction must, however, be guarded, as Gillet and Kastle found that even normal fresh milks vary in the amount of peroxidases which they contain.

*Reductase*.—Raw milk possesses reducing properties; for example, it reduces Schardinger's reagent, which consists of a solution of methylene blue containing small amounts of formaldehyd. The reductases in milk are probably of bacterial origin. On account of the bacterial origin of both the catalases and reductases in milk, the detection of these enzymes has a sanitary significance.

*Diastase (Amylase)*.—Béchamp in 1882 isolated from milk a ferment which liquefies starch and converts it into sugar as readily as diastase. These observations have not been confirmed by other investigators (Mora, Van De Velde, and Landtsheer, or Kastle).

**Thermal Death Point of Milk Enzymes.**—The influence of temperature on the activity of milk enzymes is very much like enzymes from other sources. All of this great group of substances stand in such intimate and close relation to the vital activities of the cell that all those conditions and influences which tend to destroy the one tend also to destroy the other. All of the bacteria in milk cannot be destroyed without rendering the ferments in milk inactive: but the non-spore-bearing bacteria can be killed without appreciable harm to the ferments, for in

## ENZYMES IN MILK AND THEIR THERMAL DEATH POINTS \*

Galactase—Proteolytic ferment.....	70° for 10 minutes retards its action. 76° for 10 minutes destroys its digestive power. (Babcock and Russell.) Not weakened at 60° for one hour. (von Freudenreich.) Withstands 65° for half an hour. (Hippius.)
Lactokinase—Accelerates pancreatic digestion.....	Destroyed at 73° to 75° C. for half an hour. Enfeebled at 75° for 20 minutes. (Hongardy.)
Lipase—Fat-splitting ferment.....	Destroyed at 70° C. (Harrict.) Destroyed at 65° to 70° C. (Kastle and Loewenhardt.) Withstands 60° for one hour. (Hippius.)
Catalase—Decomposes H <sub>2</sub> O <sub>2</sub> , etc.....	?
Peroxidase—Oxidizes guaiacum, etc....	Destroyed at 79° C. (Marfan.) Destroyed at 76° C. (Hippius.)
Reductase—A reducing ferment.....	Existence is doubtful in Milk.
Diastase—Converts starch into sugar...	Probably does not exist in Milk. Diastase in saliva destroyed at 65° to 70° C.

\* Compiled from Kastle.

general the ferments have a higher thermal death point than such bacteria. The activity of ferments begins to be influenced at 60° C., and is seriously affected at 70° C.; at 80° C. they are destroyed. The non-spore-bearing bacteria are destroyed at 60° C. It is, therefore, possible to destroy all the serious infections in milk, so far as man is concerned, without influencing its "life," so far as the ferments are concerned. In fact, it has been shown that milk heated to 60° C. increases the activity of some of the ferments, notably the peroxidases.

**"Leukocytes" in Milk.**—A large number of cells are normally present in milk. These are not to be regarded as the result of inflammation, unless they have the characteristics of "pus" cells. Those found in normal milk are leukocytes and degenerated epithelial cells. The number of cells in milk is greatly increased in the presence of garget; toward the end of lactation; on approaching calving time; during periods of excitement, and various other factors. A leukocytic content of 500,000 or over to the cubic centimeter, especially in a mixed milk, is regarded by the Boston Board of Health as suggestive of some inflammatory condition of the udder, more particularly if associated with streptococci. Such milk is excluded until after satisfactory veterinary inspection of the herd.

Various methods have been proposed to count the number of cells in milk. See Microscopic Examination, page 797.

**The Excretion of Drugs in Milk.**—The following drugs taken by the mouth have been found in the milk of nursing women: aspirin, iodine, mercury (calomel), arsenous acid, potassium bromid, and probably also hexamethylenamin, salicylic acid, and salicylates, ether, antipyrin, bromids, and many others; the list is very long. It is probable that opium, all volatile oils, purgative salts, and rhubarb are excreted to a certain extent in the milk. It is well known how readily the flavor of cow's milk is affected by turnips, garlic, wild onions, moldy hay and grain, or damaged ensilage. Fermented distillery waste gives a bad flavor and may also cause the secretion of small quantities of alcohol in the milk. The importance of these facts is self-evident. Cows in pastures sometimes feed on poisonous weeds, and these poisons may pass into the milk. In the production of certified milk, cows are never allowed to graze, but are given carefully selected feed. Certain substances, as ensilage, when fed to cows, cause a laxative property to appear in the milk, and thus it is possible to affect the baby through the feed of the cow.

**The Differences between Cow's Milk and Woman's Milk.**—The table (page 764) from Rotch summarizes the principal points of differences between cow's milk and human milk.

The differences between these two milks are greater than the table indicates. While cow's milk may be modified to approximate woman's milk in composition, it can never be just the same or just as good for infants.

Cow's milk is more opaque than woman's milk, although the latter may contain a greater percentage of fat. This is due to the opacity of the calcium-casein, which is present in greater proportion in cow's milk. Cow's milk is faintly acid or amphoteric when freshly drawn, but ordinarily is distinctly acid in reaction when consumed. Woman's milk is amphoteric or alkaline.

There is three times as much protein in cow's milk as in woman's milk. The reason for this is obvious, when we recall that the ratio of the growth of the calf to that of the infant is about as two to one. Furthermore, the protein in cow's milk consists chiefly of casein (3.02 per cent.) and little lactalbumin (0.53 per cent.), while woman's milk contains 0.59 per cent. of casein and 1.23 per cent. lactalbumin. The sugar in the two milks varies greatly in amount, but not in kind. Cow's milk contains almost four times the amount of inorganic salts compared to woman's milk. Of more importance, the salts in cow's milk consist mainly of the calcium and magnesium, while those in woman's milk consist mainly of potassium and sodium bases. These differences have an important bearing upon infant metabolism. There is no great difference in the average amount of fat in the two milks; however, both in woman's milk and in cow's milk the fat is the most variable constituent.

## THE DIFFERENCES BETWEEN WOMAN'S MILK AND COW'S MILK

Woman's Milk Directly from the Breast	Cow's Milk, Freshly Milked
Reaction, amphoteric (more alkaline than acid)	Amphoteric (more acid than alkaline).
pH Values, 7.1 to 7.6.....	pH Values, 6.5 to 6.8.
Water, 87 to 88 per cent.....	86 to 87 per cent.
Mineral matter, 0.20 per cent.....	0.70 per cent.
Total solids, 13 to 12 per cent.....	14 to 13 per cent.
Fats, 4.00 per cent. (relatively poor in volatile glycerids).....	4.00 per cent. (relatively rich in volatile glycerids).
Milk sugar, 7.00 per cent.....	4.75 per cent.
Proteids, 1.50 per cent.....	3.50 per cent.
Caseinogen, $\frac{1}{3}$ to $\frac{1}{2}$ of the total proteids.....	2.66 per cent.
Whey-products, $\frac{2}{3}$ to $\frac{1}{2}$ of the total proteids....	0.84 per cent.
Coagulable proteids, small proportionately.....	Large proportionately.
Coagulation of proteids by acids and salts, with greater difficulty. Curds small and flocculent.	With less difficulty. Curds large and tenacious.
Coagulation of proteids by rennet, does not coagulate readily.....	Coagulates readily.
Action of gastric juice, proteids precipitated but easily dissolved in excess of the gastric juice.	Proteids precipitated but dissolved less readily.

The curd from cow's milk is usually tougher and in larger masses than that in woman's milk. There are also differences in the antibodies, ferments, etc.

**Milk Standards.**<sup>6</sup>—The word “standard” used in this connection is not intended to imply excellence, but simply to express the lowest possible limit that the law permits for a pure or normal milk. There are at least four standards by which milk should be judged: (1) *physical standards*; specific gravity, temperature, taste, odor, etc.; (2) *chemical standards*; especially the percentage of fat and total solids; (3) *bacteriological standards*; the number of bacteria per cubic centimeter and absence of pathogens; (4) *sanitary standards* determined by inspection. Standards have also been established for pasteurization, production, transportation and handling. All are necessary for the satisfactory control of a milk supply.

Cow's milk should not contain less than 8.5 per cent. of solids not fat, and not less than 3.25 per cent. of milk fat.<sup>7</sup>

It has been found an advantage to keep the butter-fat standard relatively high and the total solids at a minimum of 12 per cent. This allows 8.5 per cent. for solids not fat, such as the proteins, milk, sugar, and inorganic salts. A 3.25 per cent. butter-fat and a 12 per cent. total solids is the minimum that should be allowed.

<sup>6</sup>The subject is fully discussed in the Reports of the Commission on Milk Standards of the N. Y. Milk Committee, U. S. Public Health Reports, May 10, 1912, and Feb. 16, 1917.

<sup>7</sup>Recommendation of the Official Agricultural Chemists, and the Commission on Milk Standards, and adopted by the U. S. Department of Agriculture and a number of states and cities.

If the law recognizes a low standard for total solids, it permits manipulation of the milk, such, for example, as adding water. It also encourages the production of milk from inferior cows. High standards encourage good dairy methods, require good feed, and place a premium upon the better breeding of milch cows.

The determination of fats and total solids is used to detect skimming or watering; however, it is possible to skim milk or water it, within limits, without the possibility of detecting it through the fats and total solids.

If dependence is placed upon the total solids, mistakes may also occur. The total solids represent the proteins, fats, sugar, and inorganic

FIG. 77.—UNSANITARY SURROUNDINGS OF A COW BARN.

salts. They may readily be tampered with. Thus sugar may be added to replace the cream that is taken off.

Bacteriological standards usually adopted are: Certified milk, not more than 10,000 bacteria per cubic centimeter; grade A milk (raw) should not have more than 10,000 bacteria per cubic centimeter; grade A (pasteurized) should not have more than 200,000 before pasteurization and less than 10,000 after pasteurization; market milk (grade B) should have not more than 1,000,000 per cubic centimeter before pasteurization, and less than 50,000 per cubic centimeter after pasteurization, and should not contain *B. coli* in 1 cubic centimeter.

**Grades of Milk.**—Milk varies greatly in sanitary quality and in nutritive value. These differences are not obvious to our unaided senses. Milk should therefore be graded just as other commodities, such as wheat, beef, fruit, coal, etc., are graded.

The grades of milk recommended by the Commission on Milk Standards of the New York Milk Committee are:

#### GRADE A

*Raw Milk.*—Milk of this class shall come from cows free from disease as determined by tuberculin tests and physical examinations by a qualified veterinarian, and shall be produced and handled by employees free from disease as determined by medical inspection of a qualified physician, under sanitary conditions, such that the bacterial count shall not exceed 10,000 per cubic centimeter at the time of delivery to the consumer. It is recommended that dairies from which this supply is obtained shall score at least 80 on the United States Bureau of Animal Industry score card.

*Pasteurized Milk.*—Milk of this class shall come from cows free from disease as determined by physical examinations by a qualified veterinarian, and shall be produced and handled under sanitary conditions, such that the bacteria count at no time exceeds 200,000 per cubic centimeter. All milk of this class shall be pasteurized under official supervision, and the bacteria count shall not exceed 10,000 per cubic centimeter at the time of delivery to the consumer. It is recommended that dairies from which this supply is obtained shall score at least 65 on the United States Bureau of Animal Industry score card.

#### GRADE B

Milk of this class shall come from cows free from disease as determined by physical examinations, of which one each year shall be by a qualified veterinarian, and shall be produced and handled under sanitary conditions, such that the bacteria count at no time exceeds 1,000,000 per cubic centimeter. All milk of this class shall be pasteurized under official supervision, and the bacterial count shall not exceed 50,000 per cubic centimeter when delivered to the consumer.

It is recommended that dairies producing grade B milk should be scored, and that the health departments or the controlling departments, whatever they may be, strive to bring these sources up as rapidly as possible.

#### GRADE C

Milk of this class shall come from cows free from disease, as determined by physical examinations, and shall include all milk that is produced under conditions such that the bacteria count is in excess of 1,000,000 per cubic centimeter.

All milk of this class shall be pasteurized, or heated to a higher temperature, and shall contain less than 50,000 bacteria per cubic centimeter when delivered to the consumer.

Whenever any large city or community finds it necessary, on account of the length of haul or other peculiar conditions, to allow the sale of grade C milk, its sale shall be surrounded by safeguards such as to insure the restriction of its use to cooking and manufacturing purposes.

These grades are gradually being adopted. Other grades are used, such as certified milk, inspected milk, market milk, etc.

There is a growing tendency to classify all milk into raw and pasteurized. This is the most significant classification from a sanitary standpoint.

The grading of milk in accordance with a simple classification, such as recommended by the Commission on Standards of the New York Milk Committee has great economic and sanitary importance. Such a system furnishes the purchaser with a ready method of knowing just what he is buying, and furthermore helps the farmer get a better price for a superior product.

**Certified Milk.**—The term “certified milk,” then, is milk of the highest quality, of uniform composition, obtained by cleanly methods from healthy cows under the special supervision of a medical milk commission. It is fresh, clean and unaltered. The term “certified milk” was coined by Dr. Henry L. Coit of Newark, N. J., who in 1892, needing good milk for his own baby, formulated a plan for the production of clean, fresh, pure milk under the auspices of a medical milk commission.

The use of the term “certified milk” should be limited to milk produced in accordance with the requirements of the American Association of Medical Milk Commissions.<sup>8</sup> The first requisite in the production of certified milk is to enlist the coöperation of a trustworthy dairyman who is willing to enter into a contract with the medical milk commission. In accordance with the terms of this contract, the dairyman binds himself to comply with the specifications set forth and in return his milk is certified.

The dairies are subjected to periodic inspections, and the milk to frequent analyses. The cows producing certified milk must be free from tuberculosis, as shown by the tuberculin test and physical examination by a qualified veterinarian, and from all other communicable disease, and from all diseases and conditions whatsoever likely to deteriorate the milk. They must be housed in clean, properly ventilated stables of sanitary construction, and must be kept clean and properly fed and cared for. All persons who come in contact with the milk must exercise scrupulous cleanliness, and must not harbor the germs of typhoid fever, tuberculosis, diphtheria, or other infections liable to be conveyed to the milk. Milk must be drawn under all precautions necessary to avoid contamination, and must be immediately cooled to 45° F., placed in sterilized bottles,

<sup>8</sup> See annual reports of this Association, also Public Health Reports, No. 85, May 1, 1912.

and kept at a temperature between 35° and 45° F. until delivered to the consumer. Pure water, as determined by chemical and bacteriological examination, is to be provided for use throughout the dairy farm and dairy. Certified milk should not contain more than 10,000 bacteria per cubic centimeter, and should not be more than thirty-six hours old when delivered.

Certified milk is raw milk and, therefore, may convey the infectious agents of disease; in fact, this has happened. Such occasional danger may be guarded against by pasteurization.

**"Standardized" or Adjusted Milk.**—The process of adjusting or standardizing milk consists in removing some of the cream or adding skim milk, with the object of purveying a product that shall contain just about the legal limit of butter fat and total solids. The method usually consists in separating the cream and recombining all or part with the addition of skim milk. The ratio of the fat to the solids not fat is changed so slightly by this adjustment that it is difficult to detect.

Such manipulation of milk is generally practiced by almost all large dealers. Sanitarians have always looked askance upon the practice. The process should be controlled and such milk distinctly labeled as to its modifications.

**Reconstructed Milk.**—Reconstructed milk is also called remade milk; sometimes "synthetic" milk. A better name is recombined milk, or reconstituted milk, for it consists of combining powdered whole milk or skim milk powder, condensed or evaporated whole milk or skim milk, with butter or milk fat and water. Machines may now be had for mixing, recombining or emulsifying these materials for the production of manufactured milk or cream. If such products are made entirely from milk constituents, they may be labeled "recombined," or "reconstructed" milk, but if any other fat is substituted in whole or in part for milk fat, then the product should be labeled "artificial milk" or "milk substitute."

There is a legitimate field for remade milk. Thus, during the World War it became necessary to find a milk supply for the new city of Nitro, West Virginia, with 25,000 and more inhabitants. The city was established in a section unsuited for dairying and no available supply of fresh milk could be found. The Government solved the problem by reconstructing milk by homogenizing butter fat and mixing this into skim milk powder and water.

The importance of sanitary control and proper labeling of these products is obvious.

**The Decomposition of Milk.**—Milk spoils in various ways as the result of bacterial growth; the kind of decomposition depending upon the kind of bacteria which predominate. Milk, as a rule, ferments, but sometimes it putrefies. In the former case the main change takes place

in the carbohydrates; in the latter the proteins are broken down. The fermentation, known as the souring of milk, is accompanied by an acid reaction and a precipitation of the casein. Putrid milk turns alkaline and bitter, owing to the formation of peptones. Sour milk is regarded as the "normal" form of decomposition, because it is the usual change and is not harmful. Putrid milk is believed at times to contain toxic substances; it is at least suspicious.

*Sour Milk—Lactic Acid Fermentation.*—Milk curdles or sours when the soluble caseinogen is thrown out of solution and precipitated as casein. The caseinogen exists in milk as a complex molecule containing calcium phosphate loosely bound to it; it also contains calcium as part of the molecular complex. The formula may be expressed thus:

The casein is held in solution (colloidal suspension) by the calcium phosphate and other soluble salts of calcium. Any chemical reaction that removes the calcium phosphate from this combination causes a precipitation of the caseinogen as casein. The casein may be precipitated by various substances, such as rennin or acids. In the normal curdling or souring of milk the casein is precipitated by lactic acid produced through the action of bacteria upon lactose. The lactic acid results from hydrolysis of the lactose as follows:

The bacteria usually concerned in the souring of milk are: *B. acidi lactici* of Hneppe, *B. lactis acidi* of Leichmann, *Streptococcus lactis* of Kruse, *B. bulgaricus* of Metchnikoff, *B. coli*, and a great number of other microorganisms capable of fermenting sugar with the production of acid. Sour milk, obtained from clean milk, is a beneficial food.

**Sour Milk and Intestinal Flora.**—Sour milk contains myriads of lactic acid bacteria. Metchnikoff called attention to the importance of a normal lactic acid flora in the large intestines, which inhibits putrefactive processes and thereby stands guard against "auto-intoxication." He recommended the use of certain bacteria in sour milk, especially *B. bulgaricus*. It is a fallacy, however, to suppose that the flora of the intestines may be influenced through ingestion of these bacteria by the mouth, even when taken in enormous numbers, as in sour milk. A sour milk diet is uncertain in its effects and often disappointing in its results.

Contrary to widespread belief, the bacterial flora of the alimentary tract is not a replica of that of the food we eat. Of the many varieties

of microörganisms gaining entrance into the alimentary tract, few succeed in establishing themselves. The diet of early infancy is rich in carbohydrates in the form of lactose. The *Bacillus bifidus* then establishes itself in the intestines. As the diet changes with age, the colon group of bacteria begins to assert itself, not because these organisms dominate in the diet, but because they, above all others, thrive as well in a medium from which carbohydrates are absent, as in one containing them. *B. coli* and related bacilli constitute nearly 60 per cent. of the viable fecal flora.

No implantation of bacilli in the alimentary tract will prove permanent unless the diet affords a suitable pabulum for the maintenance of the varieties introduced. In other words, the best way to influence the bacterial flora of the digestive tube is through diet. A carbohydrate diet favors the fermentative types and a protein diet the putrefactive types of bacteria. Kendall, in his work on intestinal bacteriology, has shown that carbohydrates spare proteins; that is, bacteria do not ordinarily break down protein in the presence of carbohydrates.

Herter and Kendall<sup>9</sup> were the first clearly to establish the fact that the chemical character of the food ingested, under normal physiologic conditions, is the fundamental factor controlling the types of bacteria vegetating in the intestinal tract. Secondary factors of almost equal weight are the rate and degree of digestion and absorption of food and the character of the end products of the digestive process. It has been demonstrated experimentally in Torrey's<sup>10</sup> investigation with dogs that, on the one hand, not all carbohydrates have an equal tendency to establish a purely fermentative intestinal flora, and, on the other hand, not all protein foods encourage putrefactive conditions in a like degree. When taken as the sole food supply by the adult, milk is very liable to produce constipation, and because of its high protein content may lead to the excessive development of putrefactive bacteria in the intestine. McCollum states that the cages of rats fed solely on milk develop an offensive odor. The addition of carbohydrates, such as starch or certain of the sugars, tends to cause the disappearance of the obnoxious flora from the alimentary tract, and favors the development instead of types which do not produce decomposition products in their action on proteins.

**Putrid Milk—Alkaline Putrefaction.**—When boiled milk is allowed to stand at room temperature, it gradually acquires an alkaline reaction,<sup>11</sup> a bitter taste, and finally curdles, yielding a soft, slimy curd. On further standing this curd is peptonized to form a somewhat clear fluid, and if these putrefactive changes are allowed to proceed for a

<sup>9</sup> *Journ. Biological Chem.*, 1910, VII, 203.

<sup>10</sup> *Journ. Med. Research*, Jan., 1919, pp. 415-447.

<sup>11</sup> Schorer found that such milk becomes less acid but seldom becomes actually alkaline in reaction.

sufficient length of time a semi-transparent liquid is obtained, having no resemblance to milk. In this form of decomposition the main change occurs in the protein constituent of the milk. The putrefactive changes of milk are undesirable and are believed sometimes to be dangerous, in that toxic substances may be produced. The principal cause of putrefaction in milk is the spore-bearing group of bacilli, belonging to and resembling the hay bacillus and also the anaërobes.

**Slimy or Ropy Milk.**—Under some circumstances certain mucilaginous substances develop in milk through abnormal fermentation. Slimy milk has been obtained of such viscosity that it could be drawn out into threads ten feet in length, and of such thinness as to be scarcely visible. In Norway such milk is esteemed a delicacy; in this country, however, it is objectionable. From a health standpoint ropy milk is not injurious unless it is slimy as a result of mucopurulent materials caused by diseased conditions in the mammary glands. The bacteria which produce ropy milk are widely distributed in nature. Of these *B. lactis viscosi* (Adametz) is the commonest organism found in Europe, and a similar organism occurs in this country. *B. lactis viscosi* is very hardy; it may find its way into the milk through the water supply of the dairy, and then becomes widely diffused and difficult to trace. It is sometimes very troublesome, but may be eradicated through cleanliness. Sometimes it is necessary to resort to disinfection. Other organisms producing sliminess in milk are the *Micrococcus freudenreichii*, two forms of streptococci, and certain of the lactic acid bacteria.

**Alcoholic Fermentation of Milk.**—This is an unusual fermentation which sometimes occurs as a result of yeasts, aided in their action by certain species of bacteria. Alcoholic fermentation of milk seldom occurs spontaneously, but may be induced by direct inoculations with certain ferments, such as those employed in the production of kumyss and kefir.

*Kumyss* was originally made from mare's milk; it is now made from cow's milk by the addition of cane sugar and yeast. *Kefir* is a similar beverage, originating in the Caucasus, where the fermentation is carried out in leather bottles and is started by means of "kefir grains" which contain yeast and various microörganisms.

**Bitter Milk.**—Freshly drawn milk sometimes has a bitter taste; in other instances milk acquires such a taste on standing a few hours. The former is due to improperly feeding the cow with such herbs as lupines, wormwood, raw Swedish turnips, cabbages, etc. The latter case is due to the growth of certain bacteria in the milk after it is drawn. The condition is undesirable, and sometimes causes much trouble for the dairyman, but it has no particular sanitary significance. According to Conn, it is a micrococcus, and according to Weigmann a bacillus, that has the power of ruining the taste of freshly drawn milk in a few hours.

This condition should be distinguished from the bitter taste of putrid milk above noted.

**Colored Milk.**—Blue milk is usually due to the *Bacillus cyanogenus*. Such milk is apparently harmless. Red milk may be due to the presence of blood coming from an injury, or acute infection of the udder. Sometimes it results from the feeding of the cow on plants containing red pigment, such as the madder root. A red color may also be produced by the *Bacillus erythrogenes*, *B. prodigiosus* and sarcinae. Red milk caused through the agency of bacteria is not known to be harmful.

**Adulterations of Milk—Skimming.**—The removal of part or all of the cream and selling the remaining fluid as whole milk is an economic fraud, and has no reference to health, except that the milk is correspondingly lowered in nutritive value. Adding skim milk is also a form of adulteration difficult to detect.

**Watering.**—The practice of watering is not nearly so frequent as formerly. If the water be pure it must be regarded more as a fraud than a health problem. The addition of water to milk lowers its specific gravity, raises its freezing point, and lowers its index of refraction and also its viscosity.

**Thickening agents**, such as chalk, calves' brains, and glycerin, have never been common practices. Gelatin or lime is sometimes used to thicken cream. Cream may also be thickened by homogenizing it. **Coloring matter** is sometimes added with the object of concealing skimming or watering or to make the milk look richer. Annatto, a vegetable dye, is most commonly used; orange and yellow azo coal-tar are also used. **Alkalies**, such as sodium, carbonate or bicarbonate, are occasionally added to milk to reduce its acidity or to improve its taste or to delay curdling. **Sweet substances**, such as saccharin or sugar, are occasionally added to milk, either to raise the specific gravity and thus disguise watering, or to disguise the sour taste of milk just on the turn.

**Chemical Preservatives.**—Chemical preservatives, such as borax and boric acid, salicylic acid, benzoic acid and benzoates, potassium bichromate, peroxid of hydrogen, fluorids, formaldehyd. and others, have from time to time been used in milk. The practice of adding any chemical preservative to milk meets with the unqualified disapproval of the sanitarian. Almost all countries prohibit the use of such foreign substances. The only proper preservatives for milk are cleanliness and cold.

**Dirty Milk; The Dirt Test.**—Practically all milk contains more or less dirt. For the most part, this dirt consists of cow feces. The presence of dirt may best be determined by filtering a pint of milk through a little disk of absorbent cotton. This produces a stain varying in intensity from a yellowish to a brownish or black spot. A Gooch crucible, a Lorenz apparatus, or simply an ordinary funnel may be used to filter

the milk. Warm milk filters much more readily than cold milk. This simple test is one of the most practical of the routine tests used for the public health control of milk supplies. The intensity of the stain and the amount of deposit upon the cotton is a tell-tale which appeals strongly to farmers and dairymen, as well as to consumers. It is a good practice to send these disks of cotton, with a letter, to the farmer, showing him the amount of dirt contained in his milk. The disks may be dried and kept with the records of the health office.

It should be remembered that milk that has been "clarified" or strained will not show the dirt test.

FIG. 78.—CONDITIONS UNDER WHICH IT IS DIFFICULT TO CLEANSE AND DISINFECT MILK BOTTLES AND MILK PAILS.

**Clarification.**—Clarification is mechanical straining by the use of centrifugal force. Clarifiers whirl the milk with sufficient force to remove heavy substances, but not sufficiently to separate the cream. Milk so treated, therefore, will not deposit a sediment on standing. The material thrown out by this method of clarification is called "separator slime," and consists of dirt, foreign particles of all sorts, bacteria, pus, blood, mucus, and also substances normally present in milk. The exact nature of the material removed is not yet fully understood.

The only advantages of clarification are that it removes visible dirt and performs the work of a strainer in a much more efficient manner. Against clarification are the facts that it does not remove pathogenic microorganisms, and hence may mislead as to the real purity of the milk; it does not remove urine or soluble portions of feces; nevertheless, the milk appears clean. It adds another process in handling the milk and hence complicates the situation; it largely destroys the value of

the dirt test, although not more so than good straining; it breaks up clumps of bacteria and distributes them through the milk. Owing to exaggerated claims, clarification may give a false sense of security.

The bacterial content of milk is apparently increased by clarification. This is due to the breaking up of bacterial clusters, which thereby increase the number of colonies on a plate. If the machine is not kept clean, contamination may take place and there may be an actual increase of the bacteria in clarified milk.

Clarification and straining have no sanitary advantages and the process should be controlled and inspected.

**Bacteria in Milk.**—As a rule, milk contains relatively and actually more bacteria than any other article of diet. Milk may, in fact, contain more bacteria than any other known substance; it frequently contains many more bacteria than are found in sewage. Mere numbers, however, need not alarm us, for it is the kind that most concerns us. By universal consent, however, milk containing an excessive number of miscellaneous bacteria is not suitable for infant feeding. Were milk a transparent food the enormous growth of microorganisms present in average market milk would be plainly visible to the naked eye.

The bacteria get into the milk from a number of different sources. Some of them are in the milk before it leaves the udder. They grow up the milk ducts into the milk cistern; hence, the fore-milk contains more than the mid-milk or strippings. It is practically impossible to obtain sterile milk directly from the teat in any large quantity. As soon as the milk leaves the teat it receives additional contamination from all objects with which it comes in contact, as the hands, the pail, the dust in the air, etc. Most bacteria get into milk with the dirt that falls from the belly and udder of the cow during milking.

The most important factors to obtain milk with a low bacterial count are: sterilized utensils; clean, healthy cows with clean udders and teats; and the use of the small top milk pail. To keep the counts low, it is necessary to chill the milk at once and to hold it at about 40° C.

Judged by the number of colonies on Petri plates, the number of bacteria in milk increases every time it is handled or exposed in any way. Separator milk contains more bacteria than the original milk. The same is true of filtered milk. This is due to the fact that while some of the visible dirt in the milk is taken out, the particles are broken up and the bacteria dispersed throughout the fluid.

Garget, or inflammation of the udder, is a very common affection of cows, and is associated with streptococci, staphylococci, lactic acid and colon bacilli, etc. Milk from a gargety udder will contain enormous numbers of the corresponding microorganisms.

For the most part bacteria do not pass a healthy udder. However,

we can place no trust in the filtering ability of the mammary gland. It is known that the virus of foot-and-mouth disease, which is ultramicroscopic, and the virus of malta fever (*Micrococcus melitensis*), and also the virus of milk sickness are almost constantly found in the milk of affected animals. On the other hand, tubercle, anthrax and other large bacilli do not pass the mammary gland unless there is a lesion of the udder.

There is occasional danger to human beings from infected udders of dairy cows when the udder infection is due to pathogenic bacteria of human origin. The danger from udder infection when the bacteria

FIG. 79.—A DARK, POORLY VENTILATED COW SHED, DIFFICULT TO KEEP CLEAN.

are of bovine origin has not yet been determined and is uncertain, with the exception of infections from bovine tuberculosis which are known to be dangerous to human beings. Every effort should be made to exclude udder infections from dairy herds. Pasteurization is a protection because it destroys the bacteria of udder infections in milk.

The bacteria in milk are not equally distributed throughout the fluid. There are more bacteria in cream than in the underlying skim milk—particularly in gravity cream. As the cream rises it mechanically carries the bacteria along with it, very much as a snowstorm sweeps the atmosphere. Milk formulae for infant feeding are often made of top milk, which, however, may contain from 5 to 100 times the number of bacteria per cubic centimeter found in the whole milk. In twenty-six samples of milk Anderson found the gravity cream contained about four times as many bacteria as the sediment layer, and about one-third as many as the whole milk. Schorer found that the cream from milk of high

bacterial count contained several thousand times as many bacteria as the underlying skim milk.

Certified milk should not contain over 10,000 bacteria per cubic centimeter; grade A not over 200,000 before, and not over 10,000 after pasteurization; inspected milk not over 100,000, and market milk not over 500,000. New York has placed the limit at 1,000,000 per cubic centimeter. Even this standard, however, has not been rigidly enforced. Boston has a standard of 500,000; Rochester 100,000.

In Washington in 1908 the average bacterial count of the market milk was 22,000,000 per cubic centimeter, as found in many hundreds of samples of the city supply. In 1909 the average was reduced to 11,000,000.

Excessive numbers of bacteria in milk indicate that it is dirty, old, or warm. Any one or any combination of these factors favors a rapid growth and multiplication of the bacteria in milk.

*The number of bacteria in milk is the best single index we have of its general sanitary character.*

Methods for determining the number and kind of bacteria in milk will be found on page 794.

**The Germicidal Property of Milk.**—The so-called germicidal property of milk has been much misunderstood. Judged by the number of colonies that develop upon agar plates, the bacteria in milk first diminish, then increase in number. This occurs only in raw milk during the first 8 or 12 hours after it is drawn. Although the bacteria seemingly decrease in numbers, they never entirely disappear. After this initial decrease there is a continuous and rapid increase, until the milk contains almost infinite numbers in each cubic centimeter. This power of milk to restrain the development of bacteria lasts from 6 to 24 hours, depending upon the temperature at which the milk is kept. When the milk is kept warm, 37° C., the decrease is pronounced within the first 8 or 10 hours; after this the milk has entirely lost its restraining action. When the milk is kept cool, 15° C., the decrease is less marked but more prolonged.

The decrease in the number of bacteria is largely apparent, being due, at least in part, to agglutination<sup>12</sup>; that is, the bacteria are not killed, they are simply grouped in clusters; this is proved by the fact that these clusters may be shaken asunder. The germicidal action of milk is specific; at most, is feeble, and is destroyed if the milk is heated above 80° C. It varies in different animals, and in the milk from the same animal at different times. It cannot take the place of cleanliness and ice, but may be taken advantage of in good dairy methods. It is true that

<sup>12</sup> Chalmers (*Jour. of Bacteriology*, V, 6, Nov., 1920) finds no common relation between agglutination and bacterial inhibition in milk, and that there is a real germicidal property in milk which is destroyed between 80° and 90° C. for two minutes.

bacteria develop more quickly in heated milk than raw milk, provided the raw milk is fresh; it should be remembered, however, that milk that is a day old no longer possesses this restraining action. The germicidal property is, therefore, ordinarily absent in market milk.

**Diseases Spread by Milk.**—The diseases conveyed through milk are: tuberculosis, typhoid and paratyphoid fevers, diphtheria, scarlet fever, septic sore throat, Malta fever, foot-and-mouth disease, and milk sickness, also some of the summer complaints of children, and the diarrheal and dysenteric diseases of adults, which are often referable to infected milk.

As a rule, milk becomes infected from human sources, sometimes on the farm, sometimes at the dairy, sometimes in transportation, and occasionally in the household. Milk-borne epidemics are due to human sources of infection. Sometimes the milk becomes infected as a result of disease of the animal, as in the case of bovine tuberculosis, Malta fever, foot-and-mouth disease, streptococcal garget, etc.

When all the facts are brought together they make a strong indictment against milk. Thus, during the five years, 1907-11, there were five milk-borne outbreaks in Boston, causing a total of over 4,000 cases of sickness.

Year	Milk-borne Epidemics in Greater Boston	Cases
1907	Diphtheria.....	72
1907	Scarlet fever.....	717
1908	Typhoid fever, about.....	400
1910	Scarlet fever, over.....	842
1911	"Septic sore throat," over.....	2,065
		4,096

In addition to the specific diseases, milk may be injurious as a result of other causes. Thus, Le Blanc has pointed out that the milk of cows in heat may cause gastro-intestinal disturbances. The toxic effects of milk and milk products of nymphomalous cows are even more marked. Milk should not be used within fifteen days of parturition. The requirement for certified milk is placed at thirty days before and fifteen days after. Such milk is apt to produce diarrhea, colic, and other digestive disturbances. Milk may further be harmful as a result of such diseases as mastitis or garget, gastro-enteritis, septic and febrile conditions of the cow. Recently it has been shown that contagious abortion of cows is due to the *Bacillus abortus*, which may contaminate milk; it is pathogenic for many animals, but there is no evidence that it is harmful to man. Schroeder and Cotton found this bacillus in 8 out of 27 samples of market milk tested.

**Tuberculosis.**—Bovine tubercle bacilli get into milk either directly as a result of tuberculosis of the udder, which occurs in from 1 to 2

per cent. of all tubercular cows, or indirectly through cow manure. In the latter case the tubercle bacilli are coughed up, swallowed, and passed in the feces. Practically all market milk contains cow feces. Occasionally milk contains tubercle bacilli of the human type from human sources. Tuberculosis in cattle is very prevalent. In Holland nearly one-tenth of all cattle killed for food are tuberculous; in Berlin 16 per cent.; in Saxony 30 per cent.; in Pennsylvania from 2 to 3 per cent. The "milk" from a tuberculous udder, when examined under the microscope, may contain as many tubercle bacilli as are ordinarily found in tuberculous sputum. The milk from a tuberculous udder of one cow may contain sufficient bacilli seriously to infect the mixed milk of 25 or 30 cows. In one case Ostertag found that 0.001 c.c. of the secretion from a tuberculous udder was sufficient to cause tuberculosis in a guinea-pig. In such a case a child would receive an enormous dose in a gill.

Tonney examined the market milk of Chicago in 1910 for the presence of tubercle bacilli. In 10.5 per cent. of 144 samples of raw milk he found tubercle bacilli in sufficient numbers to infect guinea-pigs. Of 19 samples of pasteurized milk examined none contained tubercle bacilli.

Hess in 1909 examined 107 samples of market milk in New York City, with the result that 17 of them, or 16 per cent., were found to contain tubercle bacilli.

Anderson examined 223 samples taken in the city of Washington, and reported 16, or 6.72 per cent., as positive. The tests made by the Bureau of Animal Industry of the milk in Washington disclosed 7.7 per cent. infected. Goler reports about 5 per cent. of the milk supply of Rochester, N. Y., infected.

To sum up, we have evidence from four typical American cities. A total of 551 samples of milk have been examined, in which tubercle bacilli were found in 46, making a percentage of 8.3. This may be taken as the average percentage for the entire country.

Sheridan Delepine<sup>13</sup> reports that the mixed milk of Manchester, Eng., collected at railway stations or other places than the farm, contained tubercle bacilli, as follows in the samples examined from

1897 to 1899.....	17.2 per cent.
1900 to 1904.....	10.3 per cent.
1905 to 1909.....	6.8 per cent.
1910 to 1913.....	9.0 per cent.

(years are inclusive)

Wherever these investigations have been carried out similar and sometimes higher results have been obtained, both in Europe and in this country. It is believed that the figures are an underestimate, for the

<sup>13</sup> *Jour. of State Med. Rep.*, November and December, 1914.

methods used in the laboratory are not sufficiently delicate to detect a few tubercle bacilli in milk. Unless these microorganisms are present in considerable numbers, they are apt to escape detection. In any event, it is clear that the common market milk furnished all large cities and probably most small towns very often contains tubercle bacilli.

Mohler, Washburn, and Doane found tubercle bacilli to live a year and more in cheese 220 days old. In these experiments the cheese was purposely infected and fed or inoculated into guinea-pigs at various times. Tubercle bacilli are frequently found in butter and other milk products, especially if the milk or cream of which they are made has not been pasteurized (page 785).

The relation of bovine tuberculosis to man is considered on page 166.

**Method of Detecting Tubercle Bacilli in Milk.**—It is not a simple matter to discover tubercle bacilli in milk, butter, and similar products. Direct microscopic examination for acid-fast bacilli is not satisfactory, because ordinarily there are comparatively few tubercle bacilli in mixed market milk, and furthermore, many acid-fast microorganisms other than tubercle bacilli may occur in milk.

It is not an easy task to isolate tubercle bacilli in pure culture, because the enormous number of other saprophytic microorganisms overgrow the cultures.

It therefore becomes necessary to resort to animal experimentation in order to detect and isolate tubercle bacilli. The guinea-pig is the most susceptible and suitable animal for this purpose. The material under examination may be injected subcutaneously or intraperitoneally. A number of animals should be inoculated with the sample in question for the reason that a certain proportion of them will succumb to acute infections, especially streptococci or members of the hemorrhagic septicemic group, which are often found in milk. For this reason, it is advisable to inject variable amounts for the purposes of the test. Less will be required if the sample is the milk from one-quarter of a cow than from the mixed milk of a herd.

The tubercle bacilli in milk may be first concentrated by centrifugation. Some of them will fall to the bottom with the sediment, others will rise with the cream, being enmeshed and carried by the fat globules. The cream and sediment may then be injected into guinea-pigs, either separately or mixed. It should be remembered that this process not only concentrates the tubercle bacilli, but other microorganisms that may be in the milk.

The sediment may first be treated with antiformin, which destroys many of the frailer cocci and bacilli, but spares the tubercle bacilli. Antiformin is a strong alkaline solution of chlorinated soda (see page 1421).

The guinea-pigs that survive the early pathogenic infections that

contaminate the milk should be watched for symptoms of tuberculosis—enlarged glands, loss of weight and fever. Those that do not die in two months should be tested with tuberculin. Inject 2 c.c., subcutaneously, of Koch's old tuberculin. This must be diluted back to the original strength of the bouillon culture. If the guinea-pig is tuberculous it will die within twenty-four hours—usually in from 8 to 16—with characteristic lesions of reaction about the tuberculous foci.

**Typhoid Fever.**—Of milk-borne epidemics, typhoid fever takes the lead. Typhoid bacilli may swarm in milk without altering its taste, odor, or appearance. In Washington 10 per cent. of all the cases of typhoid fever during the four years 1907-10 were traced to milk. The milk may become infected by a convalescent, a carrier, or a missed case.

Bolduan estimates that from 300 to 400 cases of typhoid fever each year come in contact with the milk supplied New York City. He further states that "the startling total of 90 to 120 typhoid carriers now probably menace the milk supply of this city." This estimate is based upon the fact that about 200,000 persons come into more or less contact with the milk from over 40,000 dairy farms. See Typhoid Fever, page 121.

Typhoid fever has also been traced to cream, ice cream, and other milk products.

Milk-borne outbreaks of paratyphoid fever have been described by Levin and Elbersen<sup>14</sup> and others.

**Scarlet Fever.**—Milk-borne outbreaks of scarlet fever are sometimes extensive and serious. The milk is practically always infected from human sources. There is a suspicion, however, that some streptococcal infections of the cow may reproduce a disease resembling scarlet fever in man. See Scarlet Fever, page 222.

**Diphtheria.**—Diphtheria bacilli in milk usually come from human sources, either cases or carriers. In a few instances ulcers upon the teat of the cow have become infected with diphtheria, and the bacilli are thus transferred to the milk. Such an occurrence, however, is unusual. As a rule, diphtheria outbreaks caused by infected milk are more limited both as to numbers and area than milk-borne outbreaks of typhoid or scarlet fever. See Diphtheria, page 195.

**Septic Sore Throat.**—The first milk-borne outbreak of "septic sore throat" recognized in this country occurred in and about Boston in May, 1911. Since then similar outbreaks have occurred in Baltimore, Concord, N. H., Chicago, and elsewhere. The infection is spreading. The Boston outbreak was carefully studied by Winslow and is so instructive that a brief account of it is given below.

Septic sore throat due to infected milk has been well known in Great Britain for thirty years. Swithinbank and Newman state that a

<sup>14</sup> *Jour. Infect. Dis.*, Feb., 1916, Vol. 18, No. 2, p. 143.

year never goes by in which there are not outbreaks of sore throat or tonsillitis due to milk or cream. These infections appear to be due to a streptococcus, several varieties having been isolated both from the milk and the throats of the patients. It is assumed that the infection usually gets into the milk from human sources, although it is suspected that streptococci eliminated by diseased udders may be responsible for some outbreaks.

Theobald Smith and J. H. Brown<sup>15</sup> have shown that there is a difference between bovine and human streptococci. The bovine streptococci produce garget in cows but do not cause tonsillitis in men; on the other hand, the human streptococci produce sore throat in man but have slight pathogenicity for cows. The human streptococci are alike in two characteristics: (1) the colonies produce immediately around them a clear hemolyzed zone on blood agar plates (horse blood); (2) these organisms ferment salicin but not raffinose or inulin. Further they are pathogenic when injected into rabbits. These organisms are called by Smith and Brown the Beta type.

Smith and Brown studied the streptococci from five milk-borne epidemics at first hand, together with cultures from the big epidemics of Chicago, Baltimore and Boston. From this work it is now clear that septic sore throat in man is of human origin, even when the disease is contracted through milk infected in the udder, for it was found that while the human streptococcus is but slightly pathogenic for cows, this organism may become implanted in the udder. This may take place through milking, wiping with infected cloths, through passing quills up the milk ducts and in similar ways. When this takes place, garget does not ensue but the streptococcus becomes seeded in the udder and may remain for six weeks or longer. In other words the cow may become a "carrier" of the human streptococcus, thus explaining why milk-borne outbreaks of septic sore throat are sometimes long drawn out.

The disease often presents a severe clinical type and may result in death. Apparently it is not readily communicable from person to person. The inflammation and swelling of the lymphoid structures of the throat and of the mucous membranes are more severe than ordinarily; edema is a feature, and many cases present pseudomembranous formation and other indications of a virulent infection. There is a sharp febrile reaction, prostration, and sometimes delirium. The duration of the disease may be prolonged, and complications occur in about one-quarter of the cases. These consist mostly of enlarged regional lymph nodes, which may suppurate; abscesses, arthritis, endocarditis, peritonitis, erysipelas, pneumonia, pyemia, acute nephritis, otitis, and other sequelae indicating the invasion of the blood with a virulent streptococcus.

<sup>15</sup> *Jour. of Med. Res.*, 1915, XXXI, p. 455. Also W. G. Smillie, "On the Streptococcus of Theobald Smith," *Jour. Infect Dis.*, Jan., 1917, Vol. 21, No. 1, p. 45.

The Boston outbreak in 1911 was characterized by its extraordinary virulence and comparative immunity of children, and high mortality among the aged and infirm. In this outbreak there were over 2,000 cases with about 48 deaths. One of the features of special interest was that the milk incriminated had always been a particularly clean, fresh, and satisfactory supply. It was obtained from tuberculin-tested cows under veterinary supervision, and the milk itself subjected to frequent chemical and bacteriological tests. The milk was bottled at the dairy, the bottles were sterilized, and many extra precautions were taken to ensure its cleanliness. For 28 years not a breath of suspicion was attached to this milk until this catastrophe occurred. It emphasizes the lesson that raw milk is apt to be dangerous milk, and our only protection against these particular dangers is through pasteurization.<sup>16</sup>

**Milk Sickness.**—Slows or trembles is a peculiar disease formerly prevalent in the central part of the United States. As forests are cleared and pastures fenced the disease becomes less frequent. It is still exceptionally met with in the valley of the Pecos River, New Mexico, in parts of Tennessee and North Carolina. The virus is communicated to man and is frequently fatal. Nancy Hanks, the mother of Lincoln, died from the disease in 1818 after an illness of a week. Little is known of the cause of milk sickness. Jordan and Harris have found a bacillus associated with the disease which they have called the *Bacillus lactis morbi*. The cause of the disease is not known.

Milk sickness is an acute non-febrile disease due to the ingestion of milk, milk products, or the flesh of animals suffering from a disease known as trembles. The disease is characterized by great depression, persistent vomiting, obstinate constipation, and high mortality.

**Malta Fever.**—Malta fever is a disease primarily of goats; secondarily of man. The infection is transmitted from goats to man through raw milk containing the *Micrococcus melitensis*. See page 407.

**Foot-and-Mouth Disease.**—Foot-and-mouth disease is an infection primarily of cattle and secondarily of man. It is caused by a filtrable virus, and is noteworthy for being the first ultramicroscopic virus discovered by Loeffler and Frosch in 1898. The infection is transmitted to man through the ingestion of raw milk, buttermilk, cheese, or whey from diseased cows. Children are not infrequently infected by drinking unboiled milk when the disease is prevalent in the neighborhood. In man the disease is mild; the symptoms resemble those observed in animals; there is fever, sometimes vomiting, painful swallowing, heat and dryness of the mouth, followed by an eruption of vesicles in the buccal and mucous membranes, and very rarely by similar ones on the fingers. The vesicles are about the size of a pea; they soon break,

<sup>16</sup> For a more detailed study of this and other milk-borne outbreaks see "The Milk Question," by M. J. Rosenau.

leaving small erosions, which rapidly heal. The disease is seldom fatal except occasionally in very weak children. See page 405.

**Food Infections.**—*Bacillus enteritidis* and all other pathogenic members of this group grow well in milk, and may thus be the cause of food poisoning outbreaks (page 701).

**Dysentery.**—This has been traced to milk in a few instances. Milk is apparently too acid for the vibrio of cholera.

**Infantile Diarrheas.**—One of the chief causes of the high infant mortality is summer diarrheas, but even these are not all due to stale, dirty, and bacteria-laden milk. Many of the diarrheal diseases of infancy are true cases of bacillary dysentery, which is transmitted in a great variety of ways. However, the improvement in the milk supply for babies has directly, and in large part indirectly, resulted in a decrease in infant mortality in recent years. In other words, improvement in infant mortality is almost wholly attributable to lessened diarrheal diseases in the summer months. Little impression has yet been made upon the other causes of infant mortality.

All the above infections may also be conveyed in fresh milk products.

**The Character of Milk-borne Epidemics.**—Milk-borne epidemics usually have an explosive onset, rise to a peak, and decline gradually. The character of the curve depends upon the amount of infection in the milk, and the manner of its distribution, the number of persons who drink it, and other factors. If the infection in the milk is dilute or attenuated, the disease crops out among a few susceptible persons who drink it. If the infection is concentrated and the milk is widely used, the curve of the outbreak will have the steeple-like character of a water-borne epidemic. The length of the epidemic varies with the period of incubation of the disease and with the length of time the milk is infected. The number of people involved may vary from a few to a hundred or several thousand. Only a single bottle of milk may be infected, and thus convey the disease to only one person; on the other hand, many gallons of mixed dairy milk may become infected and produce disease in many hundred persons. As a rule, milk outbreaks last a comparatively short time, and extend over a circumscribed area, as the disease follows the milk route. At first the disease occurs almost exclusively among users of the infected milk. Afterward secondary cases may occur.

The disease shows a special incidence among milk drinkers. It is interesting to note that sometimes only one person of a number living in the same house is attacked, and such a one is a person who drinks the milk raw.

Milk-borne diseases attack those living under the best sanitary conditions. The reason for this is that such people drink milk more freely than the poor. Milk outbreaks among the well-to-do are unnecessary tragedies to the sanitarian.

Most milk outbreaks show a greater incidence of the disease among women and children, who are usually credited with drinking more milk than men. There is apt to be a short period of incubation, probably on account of the concentration and large amount of the infection; however, the disease often runs a mild course. Multiple cases occur simultaneously in the same house. Such an occurrence is very suggestive to the epidemiologist, and frequently gives him the first hint of an impending milk epidemic.

### MILK PRODUCTS

**Condensed and evaporated milks** are concentrated by partial drying. The first really practical method was devised by Mr. Gail Borden, of White Plains, New York, who successfully evaporated milk under reduced pressure, and in 1865 obtained a patent for his process.

*Condensed* milk is not sterilized because it is preserved with sugar, and therefore contains great numbers of bacteria—often millions per cubic centimeter. *Evaporated* milk is unsweetened and must be processed in order to preserve it; it is therefore sterile, or nearly so.

Condensed and evaporated milks may be made from whole milk, skimmed, or partly skimmed milk. These are all useful and legitimate products, but they should be labeled as to the grade of the milk used, the amount of butter fat, etc. Inspection should be maintained to ensure quality and cleanliness. Condensed and evaporated milks at prevailing prices are relatively expensive when compared to fresh milk. Babies raised on these products are apt to develop scurvy unless given orange juice, tomato juice, or other antiscorbutic.

**Dried Milk (*Milk Powder*)**.—Milk may be dried in vacuo at moderate temperatures, or on revolving belts or drums in the presence of hot dry air. The presence of the fat has interposed the greatest difficulty to the complete drying of milk. In the Ekenberg process the milk is sprayed under constant pressure on the inner surface of a rotating steam-heated cylinder. The milk is thus dried in partial vacuum at a comparatively low temperature. A more frequently employed process common in the production of cheaper grades consists in spraying the previously concentrated milk on the exterior highly polished surface of revolving steel drums. Here it is almost instantaneously dried at a temperature of 230° F. and then scraped off by sharp knife blades. In the Bénévot-de-Neveu process the milk is first concentrated in a vacuum and then sprayed under great pressure into a large drying chamber where the cloud of finely atomized particles is surrounded by a current of hot air, and thereby instantly dried. The result is a powder in which most of the physical and chemical properties of the original milk are retained.

The process has been improved in recent years to such an extent that

when milk powder of good quality is mixed with water it makes a product that resembles milk in all essential particulars.

Dried milk powder may be made from skim milk, from partly skimmed milk, or from whole milk, rich in cream. The product keeps well. It has practically all the nutritive value of the original milk. The "fat-soluble A" and "water-soluble B" are not materially affected, but the antiscorbutic properties are diminished about one-half that of fresh raw milk. In other words, drying, pasteurizing and age have about the same effect on this vitamin in milk. For general cooking and food purposes, it is about the equal of liquid milk.

Dried milk has all the uses of milk. It is used as a basis of certain proprietary infant foods; it is employed in admixture with cocoa and sugar; with egg powder and sugar as a custard powder, and in various other food combinations. It is extensively used in the baking and confectionery trades. It is convenient in the household and economical so far as waste is concerned.

Babies have been fed on dried milk exclusively with good results, but not all methods of drying have yet been tested. The answer to this question must await a number of years of patient observation. In any case, antiscorbutic accessories, as orange juice, should be used. Dried milk powder makes a good food for growing children and adults.

The possibilities of dried milk promise a revolution in the milk industry. It permits milk to be produced in parts of the world where it can be made to best advantage. It saves the surplus at the spring flush. It simplifies the present cumbersome distribution to the household, and stabilizes the supply for large cities. Transportation difficulties are swept away. Sanitary control of production, and honest labeling are therefore doubly important.

**Fresh Milk Products.**—Cream, butter, buttermilk, ice cream, sour milk, fresh cheese, and other milk products may convey all the infections contained in the original milk from which they are prepared. It is known that tubercle bacilli pass into butter and may live there for months. It has also been demonstrated that infected cream may be the cause of typhoid fever, septic sore throat, and without doubt diphtheria, scarlet fever, and other milk-borne diseases.

Milk products are often made from milk that is left over or otherwise unsalable. This should be controlled by an efficient system of inspection.

The infections in fresh milk products may be guarded against by pasteurization. It is comparatively easy to pasteurize cream, for the reason that it may be heated to a higher temperature than is the case with milk without materially altering its physical properties.

**Butter.**—Butter is made by churning "gravity" cream or "separator" cream. The cream may be fresh, but is usually ripened, that is, partially sour before it is made into butter. Special cultures of microorganisms

("starters") are sometimes added to ripen the cream for the purpose of giving the butter a particular flavor. Butter is also made from homogenized milk fat.

Butter is usually "scored" in accordance with a score card proposed by Woll in which 45 points are allowed for flavor, 25 for grain (body), 15 for color, 10 for salt, and 5 for packing. The amount of fat contained in butter may be determined by the Doran method which is accurate to within one-half per cent. Warm the butter to 40° C., stir thoroughly, add about 10 c.c. of the sample into a graduated sedimentation tube, and whirl in the centrifuge for a few seconds; measure, and record. Now add about 5 c.c. of gasoline; mix, and whirl again for 15 or 20 seconds. The gasoline dissolves the fat which rises. The non-fat portion sinks to the bottom. The latter is measured and the difference represents the amount of fat. The United States regulations require that butter shall not contain less than 82.5 per cent. of milk-fat, and a renovated butter shall not contain more than 16 per cent. of moisture.

Natural butter has a refractometer index at 40° C., ranging from 1.4531 to 1.4562, usually about 1.4553. The presence of other fats that have been mixed with the butter may readily be determined by a higher refractometer reading. Coloring matter is often added to butter. The presence of coloring matter may be detected by dissolving the fat in ether and adding to separate portions dilute hydrochloric acid and sodium hydroxid. The first demonstrates the presence of the azo dyes, the second, the vegetable dyes.

Butter turns acid and rancid in time, owing to the conversion of the fat into fatty acids. Rancid butter may be renovated by washing it with skim milk or with water to which bicarbonate of soda or lime is sometimes added to neutralize the acidity. There is no particular health objection to these processes provided such butter is sold as renovated butter.

Fresh butter contains a great number of microorganisms (millions per gram). The total bacterial count diminishes with time. There may be a reduction of 85 per cent. in two weeks, and 93 per cent. in four weeks. Butter may contain tubercle bacilli, typhoid, and other pathogenic bacilli. Of 21 samples of market butter examined in Boston,<sup>17</sup> two of them were found to contain tubercle bacilli, being 9.5 per cent. of the samples examined. On account of this danger butter should always be made from pasteurized cream and labeled "butter made from pasteurized cream," not "pasteurized butter."

Petri examined 102 samples of butter at Berlin, using 408 animals for inoculation; 16.7 per cent. contained tubercle bacilli. Korn found 23.5 per cent. of 17 samples of butter at Freiberg to contain tubercle bacilli.

<sup>17</sup> Rosenau, Frost and Bryant, *Jour. of Med. Res.*, XXX, No. 1, p. 69, March, 1914.

The frequency with which tubercle bacilli are found in butter is shown in a table collected by Swithinbank and Newman.<sup>18</sup> Of 498 samples tested from different sources, 76, or 15.2 per cent., contained tubercle bacilli.

Schroeder and Cotton<sup>19</sup> have found that living tubercle bacilli will retain their infective properties for at least 160 days in salted butter when kept without ice in a house cellar.

Butter may also convey typhoid bacilli and other pathogenic micro-organisms.

*Oleomargarine* is a mixture of various animal and vegetable fats and oils otherwise used as food products, therefore the objections to the use of oleomargarine are more on the grounds of fraud and deception than in regard to nutritive value or sanitary significance. The fraud consists in selling oleomargarine as butter.

Oleomargarine made of vegetable oils does not contain growth promoting vitamins, whereas most animal fats, except lard, do. The better grades of oleomargarine contain some milk fat.

In the United States the manufacture of oleomargarine can take place only under the supervision of the internal revenue bureau: all oleomargarine artificially colored to resemble butter pays an internal revenue tax of 10 cents per pound; uncolored,  $\frac{1}{4}$  of a cent per pound. During the fiscal year ending June 30, 1910, the quantity of colored oleomargarine manufactured in United States amounted to 3,491,978 pounds; and uncolored, 85,164,655 pounds. For coloring matter anilin dyes are usually preferred to annatto or saffron.

Oleomargarine consists of a mixture of neutral lard, beef fat, and cotton-seed oil which are usually churned with milk in order to give a flavor of butter to the product. The yolk of eggs and other substances are sometimes added. In the manufacture of oleomargarine, fat from the mesentery and mediastinum is said to be sometimes employed, and this fat often contains tuberculous glands. The milk used may also contain tubercle bacilli. Morgenroth examined 20 samples of oleomargarine, some of which were of the cheap variety and some expensive. In 9 specimens tubercle bacilli were found.

*Test to Distinguish Butter from Oleomargarine.*—Place a piece of the sample, about the size of a small chestnut, in an ordinary tablespoon. In the laboratory a small dish or test tube may be used. Heat over a flame, first melting the sample to be tested, hastening the process by stirring with a splinter of wood (a match-stick). When melted, increase the heat, bring to a brisk boil, and after the boiling has begun stir thoroughly, not neglecting the outer edges.

Oleomargarine and renovated butter boil noisily, sputter more or

<sup>18</sup> "Bacteriology of Milk," p. 221.

<sup>19</sup> *Bureau of Animal Industry Cir. No. 153*, p. 38.

less like a mixture of grease and water when boiling, and produce no foam, or very little. Renovated butter produces usually a very small amount. On the other hand, genuine butter boils usually with less noise and produces an abundance of foam.

The refractometer reading gives a more accurate test. See page 805.

**Inspection.**—An efficient inspection service is a preventive measure that strikes at the root of the milk problem. A good inspection service is expensive, but is worth its cost in providing cleaner and better milk. Inspection has its limitations, for it cannot see bacillus carriers, mild cases of disease, and cannot be on hand at all places at all times. No system of inspection can be so perfect as to insure milk free from infection.

A competent system of inspection will help the farmer very much with his problems, and the educational value of such a system is one of its best features. The score-card system is an essential element in a successful inspection service.

The *score card* should be used in inspecting dairies, but dairy scores may not correspond to milk grades as determined by bacteriologic tests. The score card has advantages and limitations. It scores cleanliness and decency, but cannot score intelligence and conscientiousness. It should take equipment as well as methods into account. The system of scoring is instructive. It may serve as a basis of grading and licensing.

Inspection is particularly helpful in tracing the source of infected milk and preventing recurrences. Another important element in any inspection system is the license or permit. All persons producing or handling milk should obtain a license, which should be issued only after the person has demonstrated his capacity to handle milk in a safe and cleanly manner. The license should be renewed at least once every year.

**Pasteurization.**—Pasteurization as applied to milk consists in heating it for a short period of time at a temperature below the boiling point, followed by rapid chilling. In the language of the kitchen, pasteurization means parboiling. To the sanitarian pasteurization has but one object, viz., the destruction of pathogenic bacteria.

Milk heated to 60° C. and held at that temperature for 20 minutes will kill the viruses of tuberculosis, typhoid fever, scarlet fever, diphtheria, Malta fever, dysentery, foot-and-mouth disease; this time and temperature will also kill streptococci, staphylococci, and practically all non-spore-bearing microorganisms pathogenic for man.<sup>20</sup> To provide a factor of safety it is advisable in commercial practice to heat milk to

<sup>20</sup> De Jong and De Graef (quoted by Rullman, *Centralbl. f. Bakteriöl.*, Part 2, 1914, XLI, 269) have described seven strains of *B. coli* which survive 65° to 67° C. for 30 minutes in milk or broth. These strains would not be killed by the degree of heat commonly used in pasteurization and in consequence the

65° C. for a period of 30 or 45 minutes. The Commission on Milk Standards of the New York Milk Committee recommend:

“That pasteurization of milk should be between the limits of 140° F. and 155° F. At 140° F. the minimum exposure should be 20 minutes. For every degree above 140° F. the time may be reduced by 1 minute. In no case should the exposure be for less than 5 minutes.”

In order to allow a margin of safety under commercial conditions, the commission recommends that the minimum temperature during the period of holding should be made 145° F. and the holding time 20 minutes.

Heating milk to this temperature does not alter its taste, odor, or digestibility, does not interfere with its food value, and has the great advantage of preventing much sickness and saving many lives.

Pasteurization is not the ideal, but only an expedient. It is the simplest, cheapest, least objectionable, and most trustworthy method of rendering infected milk safe. Pasteurization, however, cannot atone for filth and should not be used as a redemption process. A pure milk is better than a purified milk; however, no one should drink raw milk that cannot be guaranteed by the health officer as safe and free from danger. Only certified milk or milk of equally high character can be regarded as reasonably safe without pasteurization. Less than 1 per cent. of all the milk found upon the market comes within the honor class. Furthermore, even certified milk has been responsible for outbreaks of diphtheria, etc.

Pasteurized milk must be handled at least as carefully as raw milk. It should be bottled by machinery immediately following the process, kept cold, and delivered promptly. Pasteurized milk sours as a result of acid fermentation, just as raw milk does. In other words, the temperatures recommended do not destroy “nature’s danger signal”—the lactic acid bacteria.<sup>21</sup>

Pasteurization is not proposed as a substitute for inspection, but as an adjunct to inspection. Inspection gives us cleaner and better, but not necessarily safe, milk. Pasteurization destroys the dangers inspection cannot see. The combination of inspection and pasteurization corresponds in all respects to modern methods of obtaining a safe water supply for a large city. The watershed, through inspection, is kept clean, but the water is filtered or purified before it is given to the consumer.

There can be no more objection to the heating of milk for the use of adults and children above the age of three years than there is to the presence of *B. coli* in pasteurized milk can no longer be taken as an index of improper pasteurization or subsequent contamination.

<sup>21</sup> Nature has no danger signal for infected milk. Pathogenic microörganisms do not alter the taste, odor or appearance of milk.

cooking of meat. Infants should receive breast milk. When this is not possible they should have the best, freshest cow's milk that can be obtained. Whether such milk is to be pasteurized, modified, or otherwise treated will vary with circumstances.

Much has been said concerning the relation of scurvy and rickets to pasteurized milk. Fresh raw milk has antiscorbutic properties, which, however, are not very active. The amount of antiscorbutic vitamin in milk varies with the feed of the cow (page 672). This

vitamin deteriorates with age, with heating, and with drying. The temperature of pasteurization reduces the antiscorbutic property of fresh milk about half. Pasteurization probably has less influence than staleness. In any case, babies raised on cow's milk should have an antiscorbutic accessory, as orange juice. The disease is readily preventable. Rickets is a disease of defective alimentation, which cannot be laid to the door of pasteurization. Pediatricians now almost unanimously recommend pasteurization, particularly in the summer time, especially for those in-

FIG. 80.—AUTOMATIC TEMPERATURE RECORDER FOR PASTEURIZERS.

infants who must depend upon ordinary market milk or milk of unknown quality.

Pasteurization is too important a public health measure to leave to individual caprice. The process should be under official supervision. Further, pasteurized milk should be labeled as such or simply "heated milk," stating the degree of heat and the length of time, and the date on which the process was done.

Pasteurization is sometimes objected to because it does not destroy heat-resisting toxins which are supposed to be in milk. The occurrence of such poisons is a mere assumption. Even if they exist in milk they would be in the raw milk as well as in the heated milk. The true exotoxins are all killed at 60° C. for 20 minutes.

Theoretically the best place to pasteurize milk is in the home. Prac-

tically the best place is at some central station, where it may be done scientifically under official surveillance.

*Methods of Pasteurization.*—There are three well-known methods by which milk may be pasteurized: (1) the flash method; (2) the holding method; (3) in the final container.

The *flash method* consists of heating the milk momentarily to a temperature of about 178° F. (81° C.) and chilling at once. This method is sometimes incorrectly called “commercial” pasteurization. It does not give uniform results, is not entirely reliable, and does not meet with the approval of the sanitarian. The method, however, is rapid and cheap.

The *holding method* consists in heating the milk to the desired temperature, say 65° C., and then holding it in a suitable tank or series of tanks at that temperature for a given period of time, say 30 or 45 minutes. This method has proved satisfactory in practice under commercial conditions.

Pasteurization *in the final container* is the perfection of the art. It is the ideal method, because the danger, however slight, of recontamination is entirely eliminated. In order to pasteurize milk in bottles the bottles must be well sealed with a tight cork and cap, or equally effective stopper. The bottles containing the milk may either be immersed in a water bath, brought to the proper temperature, held there a sufficient length of time, and then chilled; or the methods used in beer pasteurization, such as the Loew pasteurizers, may be used. In this case the bottles are subjected to a spray or shower of heated water.

Pasteurization in the bottle is especially applicable to small dealers who cannot afford automatic bottling and capping machines.

Freeman's pasteurizer for heating milk in individual feeding bottles in the home is most serviceable. The modification of Mr. Nathan Straus is shown in Fig. 81. It is used as follows:

After the bottles have been thoroughly cleaned they are placed in the tray (A) and filled with the milk or mixture used for one feeding. Then put on the corks or patented stoppers without fastening them tightly.

The pot (B) is now placed on the wooden surface of the table or floor and filled to the supports (C) with boiling water. Place the tray (A) with filled bottles into the pot (B) so that the bottom of the tray rests on the supports (C), and put cover (D) on quickly.

After the bottles have been warmed up by the steam for five minutes, remove the cover quickly, turn the tray so that it drops into the water, replace the cover immediately. This manipulation is to be made as rapidly as possible to avoid loss of heat. Thus it remains for twenty-five minutes.

Now take the tray out of the water and fasten the corks or stop-

pers air-tight. Cool the bottles with cold water and ice as quickly as possible, and keep them at this low temperature until used.

Use the milk from the bottles and by no means pour it into another vessel.

The milk should not be used for children later than twenty-four hours after pasteurization.

Emphasis is laid on the fact that only fresh, clean milk, which has been kept cold, should be used.

**The Effect of Heat upon Milk.**—The changes produced in milk by heating depend upon the degree of heat and the length of exposure.

FIG. 81.—STRAUS HOME PASTEURIZER.

Milk heated at 62.8° C. for 30 minutes does not undergo any appreciable chemical and physical change. The boiling of milk, however, produces pronounced changes. In the main, these consist of a partial decomposition of the proteins and other complex nitrogenous derivatives; diminution of the organic phosphorus and an increase of inorganic phosphorus; precipitation of the calcium and magnesium salts and the greater part of the phosphates; expulsion of the greater part of the carbon dioxide; caramelization or burning of a certain portion of the milk sugar, causing the brownish color; partial disarrangement of the normal emulsion, and coalescence of some of the fat globules; coagulation of the serum albumin, which begins at 75° C.; the ferments are killed.

Boiled milk has a cooked taste which appears at about 70° C. This is due perhaps to the decomposition of certain of the proteins in the milk. The loss of certain gases also alters the taste, so that milk heated

in closed vessels has a less pronounced flavor than if heated in open vessels.

Milk heated in the open air forms a pellicle which renews if it is removed. This scum forms when milk reaches about 60° C. It consists of:

Casein and albuminoid.....	50.86 per cent.
Fatty matter.....	45.42 per cent.
Ash .....	3.72 per cent.

Milk heated in closed vessels does not form a pellicle, even when the temperature reaches the boiling point. It seems that this pellicle is due mainly to the drying of the upper layer of the liquid.

After milk has been heated to 68° C. or over for half an hour, the cream does not rise well, if at all, owing to the increase in the viscosity of the fluid in which it is emulsified. The clusters of fat droplets which are agglutinated into masses in normal milk are broken down by heating, and the globules are more homogeneously distributed throughout the fluid.

It has been observed that cooked milk coagulates with rennin more slowly than raw milk. This effect is noted often at temperatures of 80° to 90° C., but has not been observed in milk heated to 60° C. for 20 minutes. The curd produced by rennin coagulation in cooked milk is softer, less tough, and more flocculent than that produced by rennin coagulation in raw milk. This is believed to be an advantage favoring the digestibility of heated milk. Cooked milk is said to be constipating. This is explained by the fact that cooked milk contains comparatively few bacteria and is, therefore, less irritating than raw milk.

Methods for detecting heated milk see page 808.

**The Essential Requirements for a Safe and Satisfactory Milk Supply.**—1. Cows should be healthy and free especially from communicable infections, or any febrile disease, or inflammatory condition of the udder.

2. All persons who in any way come in contact with the milk or milk apparatus should be free from communicable diseases and not be carriers. A minimum of human contact should be insisted upon.

3. The milking should be done in clean rooms, the udders washed; the hands of the milker should be clean and dry.

4. The milk should be received into clean, sterilized pails, with a small mouth so as to keep out dust and dirt which falls from the udder and belly of the cow. If strainers are used they should be cleaned or boiled morning and evening. Cans and pails should be cleaned with washing soda or alkaline powder (not soap), rinsed in clean water, and then steamed or boiled.

5. The milk should be chilled to 50° F. or under at once, and kept protected from flies, dust, odors, and contamination, in a clean milk house until collected. A wooden paddle should not be used to stir the milk. If stirred a metal paddle is preferable.

6. The milk should likewise be kept protected and cold, not higher than 50° F., in transit to the city, and protected against tampering en route. The lower the temperature the easier it will be to keep the bacterial count down.

7. All apparatus at the city dairy, such as tanks, clarifiers, separators, pasteurizers, and bottling machines, should be kept scrupulously clean and sterilized by steam.

8. Pasteurization at not less than 60° for 20 minutes, followed by rapid chilling, and the milk kept below 50° F. until delivered to the consumer.

9. The pasteurized milk to be bottled by machinery in sterilized bottles, well sealed; and delivered promptly to the consumer.

10. All bottles and cans, after use in city delivery, should be washed and sterilized before being returned to the producer in order to prevent the conveyance of infection to the dairy or country farm.

11. The milk must be graded. In this way the producer is paid for care and cleanliness and the consumer has a ready means of knowing the sanitary character of the milk he purchases. The health officer should make frequent bacterial counts, and also sanitary surveys, for the purpose of grading.

12. A sanitary code based upon good milk laws. The system should include milk products.

13. A system of licensure and inspection to insure the above requirements.

## THE BACTERIOLOGICAL EXAMINATION OF MILK

**The Number of Bacteria.**—No known method can give an enumeration of all the bacteria in milk. Some are aërobes, others anaërobes; some require alkaline, others acid media; some grow best at room temperature, others only at blood temperature; and some grow slowly or not at all upon ordinary media. The methods in use, therefore, are those which have been shown by experiments to give the highest counts and the maximum information under ordinary conditions.

For the sake of uniformity methods should follow the report of the Committee on Standard Methods of Bacterial Milk Analysis of the American Public Health Association.<sup>22</sup>

The samples must be collected and kept in such a manner as to

<sup>22</sup> *American Journal of Public Health*, Vol. VI, No. 12, Dec., 1916.

prevent either any addition of bacteria from without or multiplication of the bacteria originally present. Whenever possible, and especially in the selection of certified milk samples, an original package should be taken, placed in a suitably iced case, and brought at once to the laboratory. Samples of market milk may be collected in the same manner as water samples, in sterile, wide-mouthed, glass-stoppered four-ounce bottles. Care should be taken to secure a sample which is thoroughly representative of the milk to be examined. This may be done by pouring the milk back and forth into a sterile receptacle, or shaking the milk thoroughly with the receptacle turned upside down. In taking samples from tanks it is allowable to stir thoroughly with a long-handled dipper. Generally speaking, the shorter the time between collection and examination of milk samples the more accurate will be the results. For routine work the attempts should be made to plate within four hours of the time of collection. Too much stress cannot be laid on the importance of keeping the samples properly iced during this interval. They should be kept below 40° F., but care should be taken that they are not frozen.

The standard medium for routine enumeration of bacteria in milk is Standard Beef extract agar<sup>23</sup> adjusted according to Fuller's scale. The reaction is not to be changed if it falls between +0.5 and +1.0 per cent. Milk should always be diluted before plating, for the reason that whole milk produces a turbidity of the agar, and because the bacteria cannot well be dispersed without diluting, and the resulting colonies are so close that they interfere with each other. The milk is diluted in the proportion of 1-10, 1-100, 1-1,000, 1-10,000, 1-100,000 or 1-1,000,000. For certified milk 1-100 dilution should be used. Ordinary potable water, sterilized, may be used for dilutions. The number of bacteria present may be estimated approximately before dilutions are made by direct microscopic examination of a properly prepared sediment. Otherwise it is necessary to make a range of dilutions therefrom, selecting for record the count obtained on that plate which yields between 30 and 300 colonies. A plate containing more or less than these numbers will not give reliable results. Porous, earthenware Petri dish covers are recommended as superior to glass, since they absorb the excess of moisture and thus help to prevent spreaders. Another method of preventing spreaders is to invert the dishes and place in the glass cover of each a strip of sterile filter paper moistened with one large drop of glycerin.

The plating should always be checked by duplicate controls, and a blank plate should be made with each series for control of the sterility of the agar, water, air, Petri dishes, pipettes, and methods. The plates should be incubated at 37° C. for 48 hours, or may be grown at

<sup>23</sup> Esculin bile salt agar, lactose litmus agar, and whey agar may also be used.

21° C. for five days. Only those colonies should be counted which are visible to the naked eye or may be seen readily by a low power lens.<sup>24</sup> The result should always be expressed in round numbers. It is misleading to state that a milk contains 2,140,672 bacteria per cubic centimeter. This gives a false and exaggerated notion of the accuracy of the method. At best the results are only an average approximation. Results should be expressed in accordance with the recommendations of the Commission on Standards of the New York Milk Committee.<sup>25</sup>

The number of bacteria is the best single index we have of the general character of milk.

**The Kinds of Bacteria.**—We still lack satisfactory routine methods for determining the kinds of bacteria found in milk. If the plates are made with gelatin it will give the relative proportion of liquefiers. By the use of Endo's medium or lactose litmus agar the number of acid-producing bacteria may be determined.

To determine the number of proteolytic bacteria in milk place 1 c.c. of sterile skim milk into a Petri dish, then add the proper dilution of milk in question, and finally pour in molten sugar-free agar. Incubate 48 hours, and then wash the surface with a dilute solution of acetic acid. Count the number of colonies surrounded by a clear zone, which is taken to represent proteolysis or breaking down of the protein.<sup>26</sup>

Typhoid bacilli may be isolated on Endo's medium, and diphtheria upon Loeffler's blood serum. Other pathogens require special technic applicable to each case. The number of streptococci in milk may be estimated by the direct examination of stained smears. The chains are more readily counted if the milk is first incubated at 37° C. for 6 or 8 hours. In the estimation of streptococci only the longer chains are considered. The presence of streptococci and an approximation as to their number may also be determined by planting the milk upon the surface of blood agar and studying the fine dewdrop-like colonies.

A few streptococci will be found in most sediments from milk. They are seldom found to any great extent by direct microscopic examination of clean milk. Occasionally a sample will be found crowded with long chains. More often streptococci, if present, are in the form of diplococci or very short chains. The common interpretation is to regard the short chain varieties as probably harmless, while long chains are regarded as more apt to indicate inflammatory reactions. This is a serious mistake. There is no relation between length of chains and pathogenicity.

Ruediger points out that *Streptococcus lacticus* can be differentiated from *Streptococcus pyogenes* by means of blood agar plates. *Strepto-*

<sup>24</sup> Magnifying 2½ diameters.

<sup>25</sup> *Public Health Reports*, Vol. XXVII, 19, May 10, 1912.

<sup>26</sup> Hastings: *Cent. f. Bakt. u. Parasitenk.*, Abt. II, Bd. X, p. 384.

*coccus pyogenes* produces small colonies surrounded by a large zone of hemolysis, whereas *Streptococcus lacticus* produces green or grayish colonies with very little or no hemolysis.

*Streptococcus lacticus* has no sanitary significance, as it is found in nearly all samples of clean, soured, or fresh milk, and very often in the healthy milk ducts. *Streptococcus pyogenes*, on the other hand, seems to occur but rarely in milk, and is indicative of the existence of an inflamed condition of the udder of the cow furnishing the milk.

The Beta type of hemolytic streptococci described by Smith and Brown may be isolated from milk by the method described on page 781.

The presence of *Bacillus Welchii*, or the gas bacillus, may be determined by heating some of the milk to 80° C. for one hour in deep anaërobic tubes and then incubating the sample at 37° C. If the sample contains this microörganism it will show "stormy fermentation" with gas production within 24 hours (sometimes as soon as 6 hours), with coagulation and breaking up of the curd, some of which may be forced above the cream line, and with the development of an odor of butyric acid.

The demonstration of tubercle bacilli in milk depends upon animal experimentation. See page 779.

## MICROSCOPIC EXAMINATION

There are three methods of making a microscopic examination of milk in current use. These are convenient and practical methods of roughly but quickly determining the sanitary quality of milk, based upon its bacterial content.

(1) **The Stewart-Slack Method.**—Two c.c. of milk are placed in a glass tube closed at both ends with a rubber stopper. This is centrifuged for 10 minutes at a speed of from 2,000 to 3,000 revolutions per minute. The sediment upon the rubber stopper of the distal end of the tube is mixed with a drop or two of water and spread upon a slide in a thin, even layer, covering a space of about four square centimeters. This is dried and stained with methylene blue. The microscopic examination reveals the character of the milk as judged from the approximate number of pus cells and presence of streptococci in long chains. It has been found that the number of cocci, bacilli, or chains in the 1/12 oil immersion field, multiplied by 10,000, gives a rough approximation of the number of bacteria in a cubic centimeter of the whole milk.

The results of this method vary considerably with details of individual manipulation, with the speed of the centrifugal machine, with the time allowed for centrifugation, and other factors.

(2) **The Doane-Buckley Method.**—In this method the number of leukocytes are counted in the chamber of the Zeiss blood counter, which contains just 0.0001 c.c. Ten c.c. of milk is centrifuged at 2,000 revolutions per minute for four minutes. The fat is removed with a cotton swab and again centrifuged for one minute. The fat is again carefully removed, for any appreciable amount of fat will interfere with the counting. The supernatant fluid is now pipetted off and two drops of a saturated alcoholic solution of methylene blue are added to the sediment, which is thoroughly mixed and warmed in boiling water for two or three minutes, which favors the staining of the cells. The sediment is now diluted to the 1 c.c. mark with water. Some of this is transferred to the counting chamber and the number of cells counted with a dry lens. The number of cells in the counting chamber multiplied by 1,000 gives the number per cubic centimeter in the milk.

(3) **The Prescott-Breed Method.**—Special pipettes graduated to hold 0.01 c.c. of milk may be obtained for use under this method. After a thorough mixing of the milk, 0.01 c.c. is removed with the pipette and spread uniformly over a square centimeter on an ordinary microscopic slide. It is allowed to dry and is fixed with methyl alcohol, after which the fat is dissolved from it by the use of xylol. The smear is then stained either with methylene blue or preferably with one of the blood stains, the Jenner stain or Wright stain being useful for this purpose. If the staining is so deep as to make the specimen too opaque for proper study, it is slightly decolorized with alcohol, which removes the stain from the general sediment more readily than it does from the bacteria of the tissue cells. The stained smear is studied under a 1/12 inch immersion lens. The draw tube is adjusted so that the field of the microscope covers exactly 15 millimeters, and under these circumstances the number of bacteria present in the 0.01 c.c. is exactly 5,000 times the number found in a microscopic field. The counting of a large number of fields (100 fields) and averaging the results multiplied by this number will, therefore, give approximately the number of cells or bacteria contained in 0.01 c.c. of milk.

## CHEMICAL ANALYSIS OF MILK

**Total Solids.**—The total solids in milk consist chiefly of the fats, sugar, proteins, and inorganic salts. The United States standard requires 12 per cent. of the milk to consist of total solids, 8.5 per cent. of which shall be solids not fat, and 3.25 per cent. fat. In some states the requirement for total solids is as high as 13 per cent., in others 11.5 per cent.

**Determination of Total Solids.**—The total solids may be determined either by:

- (1) The use of Richmond's slide rule.
- (2) The Babcock asbestos method.
- (3) By evaporation and direct weighing.

*Richmond's Slide Rule.*—This is a device by which the total solids may be determined fairly accurately by the use of the formula of Hehner and Richmond. It is necessary to know the correct specific gravity and the amount of fat. From this the total solids is determined by the following formula:

$$T S = \left( \frac{G}{4} \right) + 1.2 F + .14$$

in which T S equals total solids, G the last two units of the specific gravity and any decimal. Thus, if the specific gravity is 1.0295,  $G = 29.5$ . F represents the percentage of fat. In using the slide rule the operation is conducted in two stages. First, the lactometer reading is corrected for temperature. The observed lactometer reading is brought opposite the 60° mark and the correct specific gravity read opposite the observed temperature. Second, the arrow of the slide is set opposite the observed percentage of fat, and the total solids are read off opposite the corrected specific gravity reading on the scale marked "specific gravity." The results obtained by the use of Richmond's slide rule agree quite closely with those obtained by direct weighing.

This formula may also be used to determine the percentage of fat provided the specific gravity and total solids are known.

*The Babcock Asbestos Method.*—The milk is placed upon a filter paper cartridge filled loosely with freshly ignited woolly asbestos, subjected to a temperature of 100° C. until weight is constant, and then cooled and weighed. The gain in weight represents the total solids of the amount of milk taken. The advantage in this method is that the cartridge may then be slipped into the Soxhlet extraction apparatus and used for the determination of fat.

*Weighing.*—About 5 c.c. of milk are weighed in a tared platinum dish, evaporated exactly two hours on a steam bath, the outside wiped dry, and then cooled to constant weight in a desiccator. The weight of the residue represents the total solids of the milk.

*Determination of Ash.*—The platinum dish containing the total solid residue is carefully heated in the flame, avoiding spattering and heating above a dull red glow. When the residue has become white, or nearly so, it is cooled in a desiccator and again weighed; the difference between the final weight and the original weight of the empty dish represents the amount of mineral matter in the amount of milk taken.

The ash is saved for the tests for boron compounds, carbonates, and other non-volatile mineral preservatives.

**Determination of Fats.**—The determination of the quantity of butter fat contained in milk is of considerable economic importance and is included as a routine in all milk laboratories. There are several methods by which the fat in milk may be accurately determined.

(1) *Babcock Method.*—The Babcock method is the most convenient and is sufficiently accurate for ordinary purposes. It cannot be carried out without considerable special apparatus, including a centrifuge, special graduated flasks and pipettes. The method consists in separating the fat by the addition of sulphuric acid. The mixture is centrifugalized so that the fat rises into the neck of the specially graduated flask, and the percentage may be read off directly. The sample should be well mixed by pouring back and forth just before the test. The method is carried out as follows:

In the special graduated flask are mixed:

17.6 c.c. milk.

17.6 c.c. of sulphuric acid (specific gravity 1.82-1.83).

The acid must be run slowly down the side of the flask under the milk and the whole mixed at once, without splashing, by imparting a rotary motion to the contents of the bottle. The mixture is centrifugalized for 5 minutes; boiling water is then added until the liquid rises to the bottom of the neck of the flask, and the centrifugalization is repeated for 3 minutes. Again add boiling water until the top of the column is near but safely under the top of the scale, and centrifugalize a third time for 1 minute. By this time the fat in the neck of the bottle should be clear, yellow, and liquid. The length of the column of fat is considered as extending from the bottom of the line of contact with the liquid below to the top of the meniscus above. The length of the column of fat is measured by means of a pair of dividers, which are first adjusted to the length of the column, then the percentage is read by touching one point of the dividers to the zero mark on the scale, when the upper point will indicate the percentage of fat in the milk. The mixing of sulphuric acid with the milk generates considerable heat, which should be maintained, so that at the time of taking the reading the contents of the bottle register between 55°-60° C. Care should be taken to use none but authoritatively tested and guaranteed bottles. The flasks should be emptied before the fat cools and hardens.

(2) *The Werner-Schmidt Method.*—This method is slower than the Babcock, especially when many samples are to be analyzed, but it can be done with improvised apparatus and readily procurable materials. Ten c.c. of milk are added to 10 c.c. of concentrated hydrochloric acid

in a 50-c.c. test tube, shaken, and boiled until dark brown in color. The mixture is then cooled in water and 30 c.c. of washed ether added, the stopper inserted, and thoroughly agitated. When the two layers have separated the upper layer, containing the ether and dissolved fat, may be withdrawn by means of a pipette, or blown out with the assistance of a double tube, such as is used in wash-bottles, the delivery tube extending into the ether layer almost to the line of demarcation between the ether and the acid-milk mixture. The ether containing the extracted fat is transferred to a weighing flask. The extraction is repeated with several fresh, smaller portions of ether (about 10 c.c.), and the whole of the ether used is collected in the weighed flask. The ether is then distilled off or permitted to evaporate at a low temperature. The residuum of fat is heated to constant weight in an air bath, cooled, and weighed. Since the milk is measured and not weighed, a correction must be made accordingly.

*Example.*—Amount of milk used equals 10 c.c. Specific gravity of sample equals 1.029. Weight of milk used, therefore, equals  $1.029 \times 10$ , which equals 10.29 grams. The weight of the fat found equals 0.386 gram. Percentage of the fat in the original milk is determined from the following equation:

$$10.29 : 0.386 :: 100 : x$$

$$x = 3.75, \text{ or the percentage of fat in the original milk.}$$

(3) *The Soxhlet Extraction Method.*—This is the most accurate method for determining fats in milk and other substances. The principle consists in the complete extraction of all the fat by continuous washing with ether. The only error in this method arises from the fact that substances other than fats are soluble in ether and are included in the weight. This error in milk is negligible. The process requires a coil of thick filter paper free from substances soluble in ether and alcohol, and a Soxhlet extraction apparatus. Instead of the coil of filter paper a specially prepared cartridge of filter paper which fits loosely within the cylinder of the Soxhlet apparatus may be used. When the cartridge is used it is best to plug its open end with absorbent cotton, in order to prevent the escape of fine particles of the contained substance.

A definite weight of milk, about 5 grams, is applied to the coil of filter paper or cartridge, in one of two ways. A small beaker containing the required amount is weighed and the coil is placed in it and kept there until nearly the whole has been absorbed. The coil is then carefully withdrawn and placed, dry edge downward, upon a sheet of glass. The beaker is then weighed again, and the loss in weight, which represents the amount of milk absorbed, is noted. Another method is to

weigh the beaker containing the milk and a small pipette. The necessary amount of milk is then transferred to the coil with the pipette, after which the weight of the beaker and pipette containing the remaining milk is noted. The difference represents the weight of the milk absorbed. The coil or cartridge is then dried in an air bath at 100° C. for an hour or more, when it is ready for insertion into the extractor.

The three separate parts of the Soxhlet extraction apparatus, consisting of the flask, the cylinder, and the condenser, are joined together and mounted upon a water bath or an electrically heated plate. Before the operation is begun the exact weight of the flask must be determined. The ether is then added, and as it volatilizes the vapor passes upward through the side tube into the extractor, and thence to the condenser, where it falls upon the substance to be extracted. As the process continues the condensed liquid accumulates in the cylinder and gradually rises until it reaches the bend of the siphon in the cylinder part of the apparatus. When full the siphon acts and discharges back into the flask, until the entire liquid is returned to its starting point. During its accumulation in the cylinder it dissolves the fats or other ether soluble substances which are carried in solution into the flask. The process is continued until this siphoning action repeats itself again and again as long as is necessary, so that the whole of the extracted matter is finally within the flask. The fat, being non-volatile, remains in the flask while the ether is revolatilized and sent continually on its errand. On the completion of the process the ether is permitted to collect in the cylinder, but before it reaches the level of the siphon the flask is disjoined. The remaining ether is expelled cautiously and the flask with its contents is placed in an air bath maintained at 100° C. and dried to constant weight. The increase in the weight of the flask represents the amount of matter extracted.

*Example.*—The weight of milk absorbed by the filter paper was 5.160 grams. The increase in the weight of the flask was 0.161 gram. The amount of fat present in the sample is then obtained by the following equation:

$$5.16:0.161::100:x$$

$$x = 3.12, \text{ or the percentage of fat in the milk.}$$

**Determination of Milk Sugar.**—The amount of lactose in milk may be determined chemically by the reduction of copper sulphate in Fehling solution, or optically by means of the polariscope.

(1) *Method by Fehling's Solution.*—To 25 grams of milk add 0.5 c.c. of 30 per cent. acetic acid; shake; let stand 3 minutes; then add 100 c.c. of boiling water; again shake; add 25 c.c. of alumina

cream; again shake, and let stand for 10 minutes; filter through a wet pleated paper filter and wash the residue until the washings and filtrate total 250 c.c., representing a dilution of one-tenth of the original milk; this dilutes the sugar content of the liquid to somewhat less than 0.5 per cent. This is then titrated with Fehling's solution in the usual manner, namely: fill a burette with sugar-containing liquid, place 10 c.c. of Fehling's solution (representing 0.067 gram of milk sugar) in a flask, and heat to boiling. Run in the liquid from the burette in small proportions, maintaining the contents of the flask at boiling point until the liquid in the flask loses its original blue color, which marks the end point of the reaction.

Fehling's solution is made up in two solutions: 1. Dissolve 34.639 grams of  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  in distilled water and dilute it to a liter. 2. Dissolve 173 grams of potassium sodium tartrate (Rochelle salt) in distilled water, add 100 c.c. of sodium hydrate solution of 1.393 specific gravity, and dilute the mixture with distilled water to a liter. Equal parts of solution 1 and 2 are mixed in a boiling flask of about 300 c.c. capacity. The amount of copper contained in 10 c.c. of equal parts of solution 1 and 2 requires for its reduction 0.059 gram of dextrose, or 0.067 gram of lactose.

(2) *Polariscope Method*.—The polariscope, the quantities used, and the factors employed in the polariscope method vary with different types of instruments. Perhaps the most satisfactory is the Schmidt and Haenzsch half-shadow type. This possesses the advantage of doing away with the matching of colors, and hence may be used by those who are color-blind, and even with those having normal color vision it gives the most satisfactory results.

To 70.65 grams of milk add an excess (3 c.c.) of an acid nitrate of mercury solution and mix thoroughly by shaking. The acid nitrate of mercury solution is made by adding one part of weight of mercury to two parts of nitric acid, S. G. 1.42, and, after the reaction has ceased, adding an equal volume of distilled water. The object of adding the acid nitrate of mercury to the milk is to remove the albumin and fat in the form of a curd, leaving the sugar as the only optically active constituent of the clear serum. The milk containing the acid is now diluted to 102.5 c.c. with distilled water and again thoroughly mixed. Filter through a dry pleated filter and take the polarimeter reading without delay in a 200-mm. tube. When an excess of acid nitrate of mercury is added to the sugar-containing liquid the latter quickly begins to decompose, with the evolution of gas; on the other hand, an excess must be present in order to obtain a clear, easily filtered liquid.

The percentage of lactose is the product of the factor 0.0209 (this factor is applicable to these conditions only) multiplied by the number of minutes of dextrorotation. The definite directions for this particu-

lar kind of work do not accompany the instrument used. The factor should be determined or confirmed by comparing with lactose solution of known strength. Some polarimeters are graduated directly in sugar percentages instead of degrees and minutes, in which case care must be taken that the graduations correspond to the particular form of sugar under investigation, or, if not, that a suitable correction is made.

**Determination of Proteins.**—It is not usual to estimate the proteins in a sanitary analysis of milk, since different specimens of milk vary but little in this regard, and since there is little inducement for sophistication, as far as the proteins are concerned.

(1) *Method by Difference.*—If we know the weight of total solids in milk and subtract therefrom the weight of the fat, ash, and sugar, the difference will represent the proteins. This method is sufficient for ordinary purposes. To estimate the nature of the various proteins requires special skill in organic analysis.

(2) *Kjeldahl Method.*—The milk is mixed with sulphuric acid (using mercury as a catalyzer) and digested in a flask until it is completely charred and becomes clear again. The residue will then contain all of the nitrogen in the form of ammonium sulphate, which is determined in the usual way. The total nitrogen multiplied by the factor 6.38 gives the total protein. The method is carried out as follows:

*Gunning Modification.*—An accurately weighed amount (about 5 grams) of milk is placed in a 500-c.c. Kjeldahl digestion flask and digested with 10 grams of potassium sulphate and 15 c.c. of concentrated nitrogen-free sulphuric acid. The digestion is carried out over a free flame, using care to heat gradually at first; the process is considered complete when the liquid becomes clear (about 2 hours). The contents of the flask are cooled and 200 c.c. of water and sufficient saturated sodium hydroxid solution to neutralize the acid and to make the solution strongly alkaline are added. The nitrogen, which has been converted into ammonium hydroxid, is now distilled through a block tin tube into a definite amount of standard acid, and the acid titrated back with standard alkali, using cochineal or alizarin as indicator. The amount of nitrogen can be calculated from the results. Total nitrogen multiplied by 6.38 gives total protein.

*Calculation.*—The number of c.c. of N/10 acid multiplied by 0.0014, divided by the weight of the sample of milk times 100 gives the percentage of nitrogen. 1 c.c. of N/10 acid equals 0.0014 gram of N. As the reagents always contain a certain amount of nitrogen the value of a blank determination should always be subtracted from the acid reading.

The percentage of nitrogen multiplied by the factor 6.38 gives the percentage of protein in the sample of milk.

## EXAMPLE:

50.5—No. c.c. of N/10 acid originally in receiving flask.

18.8—No. c.c. of N/10 alkali used in titration.

---

31.7

.3—Value from blank determination.

---

31.4—Total No. c.c. N/10 acid used.

.0014

---

.044—Wt. of nitrogen.

.044

— $\times 100 = .427$ . Percentage of nitrogen.

10.3

.427 $\times 6.38 = 2.72$ . Percentage of protein.

NOTE.—The factor 10.3 in the above formula is the weight of the sample of milk used, i. e., the volume (10 c.c.) times the specific gravity of the milk.

**Water.**—Milk is still frequently sophisticated by the addition of water. A watered milk may be suspected from a low specific gravity, or may be detected unerringly by the index of refraction of the milk serum.

*Refractometer Reading.*—This test depends upon the fact that the salts dissolved in undiluted milk in the concentration in which they exist in the milk serum, as prepared under standard conditions, give a reading of not less than 39 upon the scale of a Zeiss refractometer at a temperature of 17.5° C. Distilled water gives with the same instrument a reading of 15. Milk reading below 39 is certainly watered; below 40 is suspicious.

Refractometer reading is obtained as follows:

The milk serum is prepared by adding 2 c.c. of a 25 per cent. acetic acid (S. G. 1.035) to 100 c.c. of milk at about 20° C. and mixing well. Heat the mixture in a beaker covered with a watch glass to 70° C. Maintain this temperature for 20 minutes. Cool quickly to room temperature by means of cold water, and filter until nearly or quite clear. Do not discard the curd, as it can be used to test for the presence of artificial colors. The refractometer reading is taken with the filtrate at 17.5° C., this temperature being maintained by means of a large body of water at the same temperature surrounding the milk container.

If a refractometer is not at hand practically the same information can be obtained from the milk serum by taking its specific gravity with a Westphal balance or a pycnometer.

The specific gravity of the serum from normal milk is never below 1.027 and only rarely below 1.029. The addition of each 10 per cent. of water lowers the specific gravity by 0.0010 to 0.0035.

**Reaction.**—The acidity of milk is determined by titration with a solution of sodium hydroxid, using phenolphthalein as the indicator.

Take 50 c.c. of milk and add a few drops of alcoholic phenolphthalein solution. From a burette run in 0.1 normal sodium hydroxid solution with constant stirring until the pink color in the milk persists about 15 seconds. The carbon dioxid in the atmosphere fades out the phenolphthalein color by converting the sodium hydroxid into sodium bicarbonate, hence the determination must be made rapidly, and a rather faint but not very permanent pink color marks the end point.

The acidity of milk is usually expressed in terms of lactic acid, although when fresh it is caused by other organic acids. To convert the amount of N/10 sodium hydroxid solution necessary to neutralize the acidity in 50 c.c. of milk into percentages of lactic acid, multiply the number of cubic centimeters of N/10 NaOH by 0.018.

The results of these titrations are recorded in three different ways: (1) In this country the calculations are reduced to terms of lactic acid. Thus, 1 c.c. of N/10 NaOH neutralizes 0.009 gram of lactic acid; (2) in degrees of acidity, by which is meant the number of cubic centimeters of N/10 NaOH required to neutralize 100 c.c. of milk; (3) in German degrees of acidity, meaning the number of cubic centimeters of N/4 NaOH per 100 c.c. of milk. For transposition purposes the following equivalents are given:

1 degree (U. S.) of acidity.....	0.009 per cent. lactic acid
1 degree (German) of acidity...	0.0225 per cent. lactic acid
1 degree (German) of acidity... 2.5°	(U. S.) acidity

Rühm<sup>27</sup> has recommended the following test for detection of beginning acidification in mixed milks of two or more cows: Ten c.c. of 68 per cent. alcohol is added to 10 c.c. of the milk to be tested. If there is immediate coagulation the acidity is above 8°. More advanced acidity may be detected by boiling a small amount of milk for a few moments in a test tube. Coagulation appears if the acidity is above 10°. These are convenient tests that may be applied at the dairy.

The accurate way to determine reaction is to measure the hydrogen ion concentration by means of indicators, or better, by the gas-chain and potentiometer. The pH values of fresh cow's milk range between 6.5 to 6.8; fresh mother's milk varies between 7.1 and 7.6.

Milk has a variable acidity when it coagulates; that is, when it throws its casein out of solution. Milk containing about 0.225 per

<sup>27</sup> Rühm: *Zeitschr. f. Fleisch u. Milch-hyg.*, Vol. XX, 1910.

cent. of acid will coagulate upon heating. This may be prevented by first neutralizing with an alkali, such as sodium carbonate. The amount of acidity in a particular sample of milk is no safe criterion as to whether it will coagulate or not during pasteurization. This can only be determined with certainty by first testing a small portion.

**Specific Gravity.**—The specific gravity of milk is taken either (1) with the lactodensimeter. (2) with the Westphal balance, or (3) upon an ordinary chemical balance, with a pycnometer.

*The Querenne lactodensimeter* is recommended for the determination of the specific gravity. It is made like an ordinary aërometer and divided into degrees which correspond to a specific gravity from 1.014 to 1.040, or only from 1.022 to 1.038, since by the latter division a greater space is gained between the different degrees without unduly lengthening the instrument. From such a lactodensimeter one can easily read off four decimal places.

The milk, the specific gravity of which is to be determined, is well shaken and poured into a high-class cylinder of suitable diameter; the lactodensimeter is dropped in slowly, in order to prevent its bobbing up and down. (The bulb should be free from adhering air bubbles.) The figures on the stem are the second and third decimals of the numbers of the specific gravity, so that 34 is to be read 1.034. For this examination the temperature of the milk must be 15° C. (60° F.); if it is not, the specific gravity of the milk at 15° C. must be calculated from the specific gravity found and from the temperature, for in milk inspection and analysis this is the standard.

*Westphal Balance.*—This instrument is more accurate than the lactometer. It is in equilibrium when the sum of the weights equals the specific gravity of the liquid.

To use this instrument, dry the plummet and balance the arm in the air; then fill the cylinder with the sample. Now place the plummet in the milk and balance the weights. The large weights represent the first decimal place; the second size, the second decimal place; the third size, the third decimal place; and the fourth size, the fourth decimal place. The specific gravity is the sum total, as shown by the notches on the arm of the balance.

EXAMPLE:

	Notch	Value
Largest size weights.....	9	.9
Largest size " .....	1	.1
Second size " .....	3	.03
Third size " .....	2	.002
Fourth size " .....	4	.0004

---

1.0324 = Specific Gravity

Correct for temperature by means of the following table:

*Table for correcting the specific gravity of milk according to temperature. (Adapted from the table of Vieth.)*

Specific Gravity	10°	11°	12°	13°	14°	15°	16°	17°	18°	19°	20°
1.027	26.1	26.2	26.4	26.5	26.7	26.9	27.1	27.4	27.5	27.7	28.0
28	27.0	27.2	27.4	27.5	27.7	27.9	28.1	28.4	28.5	28.7	29.0
29	28.0	28.2	28.4	28.5	28.7	28.9	29.1	29.4	29.5	29.8	30.1
30	29.0	29.1	29.3	29.5	29.7	29.9	30.1	30.4	30.5	30.8	31.1
31	29.9	30.1	30.3	30.4	30.6	30.9	31.2	31.4	31.5	31.8	32.2
32	30.9	31.1	31.3	31.4	31.6	31.9	32.2	32.4	32.6	32.9	33.2
33	31.8	32.0	32.3	32.4	32.6	32.9	33.2	33.4	33.6	33.9	34.2

DIRECTIONS: Find the observed specific gravity in the left-hand column. Then in the same line, and under the observed temperature, will be found the corrected reading.

Taking the specific gravity of the whole milk does not of itself detect either watering or skimming, since, if these practices are done artfully, the specific gravity of the milk may remain unaltered. The specific gravity of normal milk serum is about 1.0287.

**Field Tests.**—There are several rough and ready milk tests useful in the field: (1) The Wisconsin curd test, for flavors, odors and dirtiness; (2) the dirt test, for visible dirt; (3) the bacterial count, by microscopic examination; (4) the Farrington quick acid test for reaction; (5) specific gravity; (6) temperature.

**Heated Milk.**—Milk that has been heated above 79° or 80° C. may be detected by the fact that the enzymes are killed. Several methods are used; the most convenient, perhaps, is Dupouy's method. A few drops of a freshly prepared solution of diamidobenzene in water (1-4) and a little hydrogen dioxid are added to 5 c.c. of milk. With raw milk a coloration appears, while with milk that has been heated to 79° C. or over no color is produced. Other tests, such as the Storch method or Arnold's guaiac method, are described below under "Tests for Enzymes."

A test for heated milk has recently been devised by Frost who finds that the leukocytes in raw milk do not stain with methylene blue, whereas these cells in heated milk stain well, especially the nuclei, and are smaller.<sup>28</sup>

Van Slyke has shown that heated milk contains little CO<sub>2</sub>, as compared to unheated samples. Milk from the cow contains 4 to 5 per cent. CO<sub>2</sub>, seldom less than 3.5 per cent. After pasteurization, the amount drops to 2 per cent., and is never over 2.5 per cent.

**Tests for Enzymes, and Their Significance.**—The following tests are those most frequently used:

**Catalase Test.**—Ten c.c. of the milk to be tested is mixed with

<sup>28</sup> J. A. M. A., March 6, 1915, also.

10 c.c. of a 3 per cent. (by volume) hydrogen peroxid. The mixture is placed in a Lobeck tube and the stopper tightly inserted. Then the tube for measuring the liberated oxygen is filled with water and inserted into the perforated stopper, pushing out the small hard rubber button. The mixture of milk and hydrogen peroxid is immersed up to the stopper in a water bath at 37° C. and left there for two hours. The oxygen that is liberated replaces the water in the graduated tube on which the readings are made. Larger quantities of milk (15 c.c.) and less hydrogen peroxid (3 c.c.) give more satisfactory readings for pasteurized milk.

- According to Auzinger, the liberation of much gas by this test occurs (1) with physiologically changed milk, as is the case with colostrum and with milk from old milkers; (2) in the case of pathologically changed milk, as in mastitis and other febrile diseases; or (3) in milk containing a large number of bacteria.

The test for catalase, therefore, is of assistance in detecting old, bacteria-laden, or abnormal milk.

*Reductase Test.*—(1) Schmidt-Muller or Slow Reductase Test.—The reagent is made by adding 195 c.c. of distilled water to 5 c.c. of a saturated alcoholic solution of methylene blue (zinc chlorid double salt). This reagent should be boiled every day before using. The test is made by adding to 20 c.c. of milk in a test tube 1 c.c. of the reagent, mixing, sealing with melted paraffin, and then incubating at 45° C. in a water bath. According to Rühm,<sup>29</sup> fresh milk remains blue for 12 hours or more, and “infected” milk decolorizes in less than one hour. Reductases, according to Rühm, are increased by acid-forming bacteria, but not by alkaline producers. Auzinger,<sup>30</sup> who uses 0.5 c.c. of the reagent in 20 c.c. of milk, states that, on holding the mixture at 38° to 40° C., milk not decolorizing in seven hours contains less than 100,000 bacteria per c.c.; that which decolorizes in 2 to 7 hours contains 100,000 to 300,000; and that which decolorizes in 1/4 to 2 hours contains 300,000 to 20,000,000 bacteria per c.c.

(2) Schardinger or Hastened Reductase Test.—The reagent is made by adding 5 c.c. of 40 formaldehyd, 5 c.c. of saturated alcoholic solution of methylene blue (zinc chlorid double salt) to 190 c.c. of distilled water.

The test is made by adding to 10 c.c. of milk, 2 c.c. of the reagent in a test tube, mixing well, sealing with melted paraffin, and holding at 37° C. in a water bath. By the test, according to Auzinger,<sup>30</sup> good milk reduces the color in 8 to 12 minutes, milk rich in bacteria reduces in 5 minutes or less, and when colostrum is present two or more hours are required.

<sup>29</sup> Rühm: *Zeit. f. Fl. u. Milch-hyg.*, Vol. XX, 1910.

<sup>30</sup> Auzinger: *Ibid.*, Vol. XX, 1910.

To test for heated milk: add 20 c.c. of the milk to 1 c.c. of the reagent; seal with liquid petroleum, and incubate at 45° to 50° C. Raw milk will decolorize this reagent in less than 20 minutes; pasteurized milk will take a longer time.

Of the two reductase tests, according to Schardinger,<sup>31</sup> reduction by the slow method is due to ferments produced by bacteria, while by the hastened method reduction is due to the natural ferments of milk.

The slow reductase test is of assistance in detecting old milk, and the hastened reductase test offers a convenient and reliable method for detecting and testing the efficiency of pasteurization.

*Storch Test.*—To about 5 c.c. of milk in a test tube add a drop of 0.2 per cent. solution of hydrogen peroxid containing 0.1 per cent. sulphuric acid, and 2 drops of a 2 per cent. aqueous solution of paraphenyldiamin hydrochlorid. Mix. A positive reaction consists in the rapid production of a blue or dark-violet color. The paraphenyldiamin hydrochlorid does not keep well and should be recently prepared. If the milk is sour it must first be made alkaline with limewater. Raw milk gives a positive reaction at once; milk that has been heated to boiling gives no reaction.

*Peroxidase Reaction.*—(1) Rothenfusser's Test:<sup>32</sup> Dissolve 1 gram of *p*-phenyldiamin hydrochlorid in 15 c.c. of water. Dissolve 2 grams of crystallized guaiacol in 135 c.c. of 96 per cent. alcohol. Mix the solutions and keep in an amber-colored bottle. To 10 c.c. of milk add 0.5 c.c. of the above reagent and 3 drops of 3 per cent. hydrogen dioxid. A blue-violet coloration is developed in raw milk and if the milk has been heated to a sufficiently high temperature no color is produced. This reaction is scarcely delicate enough to detect commercially pasteurized milk.

(2) The Benzidin Test:<sup>33</sup> Dissolve 4 grams of benzidin in 100 c.c. of 96 per cent. alcohol. To 10 c.c. of milk add 1 c.c. of this reagent, 3 drops of 30 per cent. acetic acid and 2 c.c. of 3 per cent. hydrogen dioxid; a blue coloration is produced with raw milk and none with milk heated to a sufficiently high temperature.

*Bellei Test.*—The test is made by adding to 10 c.c. of milk 3 drops of 1.5 per cent. aqueous solution of ortol and two drops of 3 per cent.  $H_2O_2$ .

### TESTS FOR THE ADULTERATION OF MILK

**Coloring Matter.**—To 150 c.c. of milk, add 5 c.c. of 25 per cent. acetic acid in a large porcelain casserole and curdle over the Bunsen

<sup>31</sup> Schardinger: *Arch. f. Kinderheilk.*, Bd. 58, H. 5-6.

<sup>32</sup> *Milchwirtschl. Zentr.*, VI, 468.

<sup>33</sup> *Z. Nahr. Genussm.*, XVI, 172.

flame with the stirring rod. The curd can nearly always be gathered in one mass which is much the easier method of separation, the whey being simply poured off. If, however, the curds are too finely divided in the whey, the separation is effected by straining through a sieve or collander. All of the annatto or coal tar dye present in the milk treated will be found in the curd, also part of the caramel. The curd pressed free from the adhering fluid is picked apart if necessary and shaken in a tightly corked flask with about 50 c.c. of ether, in which it is allowed to soak for several hours or over night, or until the fat has been extracted and with it the annatto.

If the milk is uncolored or has been colored with annatto, on pouring off the ether the curd should be left perfectly white. If, on the other hand, anilin orange or caramel have been used, after pouring off the ether the curd will be colored more or less deeply, depending on the amount of color employed. In other words, the annatto is extracted by ether, caramel and anilin orange are not.

Ether Extract:	Extracted Curd:	
Evaporate off the ether on the water bath, make the residue alkaline with NaOH and pour on a wet filter. After the solution has passed through, wash off the fat and dry the filter, which, if colored orange, indicates the presence of annatto. Confirm with $\text{SnCl}_2$ which will give a pink color.	1.—If colorless indicates the presence of no foreign coloring matter other than that in the ether extract.	
	2.—If orange or brownish, indicates the presence of anilin orange or caramel. Shake the curd in a test tube with conc. HCl.	
	If the solution gradually turns blue means Caramel. Test whey of original milk and confirm.	If orange and immediately turns pink, it is Anilin-orange.

**Formaldehyd.—HCl Test.**—Commercial HCl (sp. gr. 1.2) containing 2 c.c. of 10 per cent.  $\text{Fe}_2\text{Cl}_6$  per l., is used as a reagent. Add 10 c.c. of this acid reagent to an equal volume of milk in a porcelain casserole, and heat slowly over a free flame nearly to boiling, holding the casserole by the handle and giving it a rotary motion to break up the curd. The presence of formaldehyd is indicated by a violet coloration, varying in amount and depth with the amount of preservative present. By this test, formaldehyd can be detected readily in as high dilution as one part in 250,000 parts of milk.

**$\text{Na}_2\text{CO}_3$  and the Carbonates.**—For 0.1 per cent. or more, take 10 c.c. of milk and mix with an equal volume of alcohol. To this add a few

drops of a 1 per cent. solution of rosolic acid. A rose red color proves the presence of carbonates, while pure milk gives a brownish-yellow color.

The addition of acid to the residue or ash, if it causes an effervescence, proves the presence of carbonates.

**Benzoic Acid.**—Shake 5 c.c. of HCl with 50 c.c. of milk in a flask until it is well curdled. Add 150 c.c. of ether, cork the flask tightly and shake well. Extract the emulsion which forms by means of the centrifuge or extract the curdled milk by gently shaking with successive portions of ether, avoiding forming an emulsion. A volume of ether largely in excess of that of the curdled milk has been found to be less apt to emulsionize. Transfer the ether extract to a funnel and extract the benzoic acid from the fat by shaking out with dilute  $\text{NH}_4\text{OH}$  which takes out the former as ammonium benzoate. Evaporate the ammonia solution over the water bath until all free ammonia has volatilized, but before getting to dryness add a few drops of the  $\text{Fe}_2\text{Cl}_6$  reagent. The characteristic flesh-colored precipitate indicates benzoic acid. Care should be taken not to add the  $\text{Fe}_2\text{Cl}_6$  until all the ammonia has been driven off, as otherwise a precipitate of  $\text{Fe}_2(\text{OH})_6$  is formed.

**Salicylic Acid.**—The procedure is the same as for benzoic acid, except that the addition of  $\text{Fe}_2\text{Cl}_6$  gives a violet color.

**Boric Acid and the Borates.**—To 100 g. of the milk sample, add 1 or 2 g. of NaOH and evaporate to dryness on the water bath. Char the residue thoroughly and boil with 20 c.c. of water, adding HCl drop by drop until all but the carbon is dissolved, and then add 1 c.c. in excess. Moisten a piece of delicate turmeric paper in the solution. If borax or boric acid is present, the paper on drying will acquire a peculiar red color which is changed to a dark blue-green by  $\text{NH}_4\text{OH}$ , but is restored by acid.

**Simple Modification:** In a porcelain dish, mix 1 drop of milk, 2 drops of conc. HCl, and 2 drops of sat. tr. of turmeric. Dry in the water bath, cool and add 1 drop of  $\text{NH}_4\text{OH}$  by means of a glass rod. A slaty blue color is produced if borax is present.

**Cane Sugar.**—1. Boil 5 to 10 c.c. of the sample with about 0.1 g. of resorcin and a few drops of HCl for a few minutes. A rose red color shows the presence of cane sugar. Or:

2. Mix in the test tube, 10 c.c. of the suspected milk with 0.5 g. of powdered ammonium molybdate. Ten c.c. of milk of a known purity or 10 c.c. of a 6 per cent. lactose solution are treated in a similar way for comparison. Both tubes are placed in the water bath and the temperature gradually raised to  $80^\circ \text{C}$ . An intense blue color shows the presence of cane sugar. If the temperature is raised to boiling, the pure milk or the sugar solution may turn a blue color.

**Starch.**—A small quantity of milk is heated in a test tube to boiling,

cooled, and a drop of Lugol's solution is added. Blue discoloration shows the presence of starch.

## CHAPTER III

### ANIMAL FOODS: MEAT, FISH, EGGS, ETC.

#### MEAT

The universal consumption of fresh meat as a daily article of diet by civilized man is of more recent origin than is generally supposed. McCulloch<sup>1</sup> states that "so late as 1763 the slaughter of bullocks for the supply of the public markets was a thing wholly unknown, even in Glasgow, though the city then had a population of 30,000." In the past decade or two the consumption of meat has increased enormously, especially in the United States and England, owing to the development of efficient refrigerator processes, canning, and improved facilities of transportation. The annual per capita consumption of meat has almost doubled during the past half century.<sup>2</sup>

*Per capita and proportional consumption of dressed meat in United States, United Kingdom, Germany, and France*

[The Twenty-eighth Annual Report of the Bureau of Animal Industry, 1911]

Kind of Meat	United States (1909)		United Kingdom (Average, 1906-1908)		Germany (1909)*		France (1904)	
	<i>Pounds</i>	<i>Per Cent.</i>	<i>Pounds</i>	<i>Per Cent.</i>	<i>Pounds</i>	<i>Per Cent.</i>	<i>Pounds</i>	<i>Per Cent.</i>

Pork (including lard)...	78	45	33	28	67	59	26	33
Total ...	172	100	119	100	113	100	80	100

\* The farm slaughter in Germany is for 1907.

**Structure and Composition of Meats.**—Meat is composed of muscular fibers, and the structures intimately associated with them, such as connective tissue, blood vessels, nerves, lymphatic vessels, and more or less adipose tissue.

The toughness of meat is due to the thickness of the walls of the muscle tubes and excess of connective tissue which binds them together,

<sup>1</sup> "Statistical Account of the British Empire," Vol. II, p. 502.

<sup>2</sup> Thompson: "Practical Dietetics."

hence the flesh of young domesticated animals is usually more tender than that of old or wild animals.

The flavor of meat varies with the animal's age, its food, breed, and condition when killed. The meat of male animals is usually more highly flavored than that of females. The flesh of service boars and of sexually mature buck goats is so highly flavored as to be unfit for food.

The muscle tissue of an animal consists of highly specialized tissue, whose chief function is to produce mechanical work through contraction. It is in addition a storage organ in which glycogen, a form of starch, and also fats are stored as reserve foods. It contains but little of cellular structures in the sense that the glandular organs, such as the liver, kidney, pancreas, etc., do. Chemical analysis shows the muscle to consist, aside from the reserve foodstuffs, principally of water, protein and salts. The glandular organs yield a high content of nucleic acid, while the muscle tissue yields but little in proportion to its weight. The inorganic content of the muscle tissue resembles that of the seed of the plant, rather than the leaf, both in amount and in relative proportions among the elements (McCollum).

Meat contains albuminoids and gelatinoids; the latter through action of hot water or steam are converted into gelatin. In addition meat contains the following nitrogenous substances: syntonin, myosin, muscle albumin, serum albumin, and numerous extractives, such as creatin, creatinin, xanthin, hypoxanthin, lactic acid; and small quantities of inosite and glycogen.

Meat at once after slaughter has an alkaline reaction, is tough, and possesses a sweetish and rather unpleasant flavor. Rigor mortis soon sets in, accompanied by the following changes: the reaction of the meat turns acid, owing to the development of sarcolactic acid; the connective tissue and fibers are softened as the result of autolytic enzymes and also as a result of bacterial action. While the meat becomes more tender, it also develops pleasant flavors. It is, therefore, not advisable to use meat at once after slaughter, but it should be allowed to hang two or three weeks under adequate refrigeration. It is important during this time to preserve the meat from contamination with pathogenic microorganisms and to retard the growth of the saprophytes.

**Nutritive Value of Meat.**—The nutritive value of meat depends mainly upon the presence of proteins and fats. Nitrogenous extractive matters, such as creatin, xanthin, etc., sometimes called meat bases, are formed by cleavage of the proteins, but are of little value as foods. These nitrogenous extractives are present in about the same amount in both red and white meats, with the single exception of venison, which contains the smallest amount.

Corresponding with the specialized function and the peculiarities in composition of muscle, we find that the dietary properties of meat are

comparable with the seed rather than the leaf of plants; in fact, muscle tissue differs markedly from the seed in only one respect when considered as a foodstuff, namely, in the quality of its proteins. The proteins of meat are complete, those of seeds incomplete. Both meats and seeds are poor in inorganic salts, which are necessary in the diet. Both muscle and seeds are relatively poor in "fat-soluble A" as compared with such foods as milk, egg yolk, and the leaves of plants. Meat is an admirable source of protein of good quality, but it is not an economical food. It is appetizing, satisfying and stimulating. The condimental value of meat is very high. A very common dietetic error is to eat too much meat.

Carnivora maintain a good state of nutrition because they suck blood from the large veins of the neck and their second choice is the liver and other glandular organs. Muscle tissue is only eaten after these have been consumed. Calcium is obtained through gnawing off the softer parts of the extremities of the bones.

*Beef extracts* are nothing more or less than a soup or soup stock specially prepared from beef. They first became generally known through the researches of Liebig, and are now an important article in commerce. The composition of the ordinary beef extract of commerce contains from 15 to 20 per cent. of moisture, from 17 to 23 per cent. ash, and from 50 to 60 per cent. of meat bases. These meat bases are the soluble nitrogenous contents of meat. They contain only a trace of soluble albumin, albumoses, and peptone. The chief meat bases which form the principal part of the substance are creatin, creatinin, xanthin, carnin, and carnic acid. It is, therefore, evident that meat extracts contain little nutritive matter, although this, being in a state of solution, is probably more readily absorbed than a similar amount of other nutritives in the form of ordinary meat. Wiley properly points out that the claim made by manufacturers that one pound of extract contains the nutritive properties of many pounds of meat is misleading. Such a statement is absurd upon its face, and should not be allowed to go unchallenged. These extracts may be useful as stimulants or as condiments, or as a means of speedily introducing a soluble nutriment in the case of disease, where it is extremely important that even small amounts of nutritious material should enter the body.

A distinction should be made between beef extract and beef juice. *Beef juice* is obtained by strong pressure and is concentrated *in vacuo* to the proper consistence, or it may be freshly prepared in the household. Beef juice contains much more albuminous nutrient material than beef extract, provided it is not coagulated by heat and separated out.

**Sources of Meat.**—The principal source of meat is from cattle, sheep, and swine. In many places the flesh of horses, dogs, and cats is eaten. In Germany horses and dogs are slaughtered and regularly inspected

for human food. The meat of these animals is also used in other countries that have long been flesh hungry. There is no sanitary objection to the use of such meat. Horse meat, when eaten in ignorance of its true character, makes no unpleasant impression. In Paris, Vienna, and other cities large quantities of horses, mules, and donkeys are slaughtered for food. It was formerly difficult to distinguish horse meat, but the meat of any species can now be readily diagnosed by means of the specific precipitins. For this test see page 589.

The flesh of fish is ordinarily not classed as meat, but it has the same muscular structure, and similar chemical composition and nutritive value (page 839). The different kinds of meat may be detected by physical, microscopical, chemical, or biological tests. Ordinarily meats from different animals may be distinguished by their odor or taste. Microscopically the fibers resemble each other so closely that this test is not to be relied upon. Meat varies somewhat in chemical composition from different species, from different animals of the same species, and even from different muscles in the same animal. The principal difference in the chemical composition of meats from animals of different species consists in the glycogen and fat content. Thus, horse meat contains considerably more glycogen than beef. The glycogen test, however, is not reliable because it may be changed as a result of bacterial action.

The fats of different animals have different physical and chemical characteristics. The fats crystallize in different forms and have different melting points; also the fatty acids derived therefrom. A careful examination of the fat, therefore, will lead to an approximate degree of knowledge concerning the character of the flesh from which it has been derived. For instance, lard and beef fat are easily distinguished from each other.

**The Recognition of Spoiled Meat.**<sup>3</sup>—The recognition of spoiled meat that is also injurious to health is a very difficult task. Meat that is decomposed, putrid, or offensive, and thus objectionable to the senses, needs no further condemnation. The most serious infections and poisons in meat, however, do not, as a rule, affect its appearance, odor, or taste. Infections with *B. enteritidis* or other bacilli in this group do not alter the appearance of the meat. Certain putrefactive changes brought about by bacterial action, which give the high or gamy taste so much prized by epicures, appear not to be injurious. Dogs and other carnivora prefer putrid flesh.

Meat inspectors are usually instructed to condemn meat that has not a red, fresh appearance, especially if it has become brownish or greenish. The meat is to be condemned if, upon pressure, much fluid of abnormal color or of alkaline reaction exudes; if the fat is not yellow

<sup>3</sup>See "Meat Industry and Meat Inspection," Leighton and Douglas.

and firm, especially if soft and gelatinous; if the marrow of the femur is not firm and rose-colored and has become soft and brownish. Spoiled meat under the microscope shows obscurity of the cross striations of the muscle fibers and numerous bacteria. For a further discussion of this subject see Meat Inspection, and also the various diseases which render meat unsuitable or injurious as food.

**Prevention.**—The prevention of infections and poisoning from meat and meat products depends, first of all, upon the health of the animal, next upon the mode of death, and finally upon the methods of butchering, preserving and handling the flesh. Careful attention to every detail is necessary all along the line. Cleanliness approaching surgical methods on the part of the butcher during the preparation, transportation, and handling of the meat is called for. A careful system of meat inspection is a sanitary safeguard. Thorough cooking is the most important protection we have against infection.

Meat should not be eaten raw, even where there is a carefully conducted inspection by trained experts. Individual cysticerci (tapeworm larvae) are very easily overlooked, and one is enough to bring forth a tapeworm. It is also not possible to examine all hogs, particularly those slaughtered in country districts, for trichina, and even where this is done with care the method does not afford complete protection. It is again emphasized that some of the more serious bacterial infections do not alter the color, taste, or appearance of the meat in any way. Raw meat does not have a higher nutritive value than cooked meat, but may be more easily digested.

Special measures of prevention will be discussed under each infection.

**Meat Preservatives.**—The regulations of the U. S. Department of Agriculture permit the addition to meat or meat food products of the following substances: common salt, sugar, wood smoke, vinegar, pure spices, saltpeter, and benzoate of soda, which must be declared on the label. Only such coloring matters as may be designated by the Secretary of Agriculture may be used.

The adulterants most commonly used in meats are saltpeter, boracic acid, borax, sulphite of soda, and benzoic acid (page 741).

### MEAT INSPECTION \*

The purpose of meat inspection is to eliminate diseased or otherwise bad meat from the food supply; to see that the preparation of meats and meat products is cleanly; to guard against the use of harm-

\*Collateral reading: Edlemann, "Meat Hygiene." Translated by Mohler and Eichhorn, Lea & Febiger, 1911. Ostertag, "Handbuch der Fleischbeschau," Stuttgart, 8th Edition, 1914.

ful dyes, preservatives, chemicals, or other deleterious ingredients; to prevent the use of false and misleading names or statements on labels: in short, to protect the health and the rights of the consumer. Sanitary and economic principles are the underlying factors in sound food inspection service. The necessity for this inspection is accentuated by the fact that the producer and consumer are often separated by great distances, and further there are often several middlemen between the two. A good system of food inspection is doubly necessary in the case of meat and milk, because of all foods they are most apt to carry infections and are so readily decomposable.

An efficient meat inspection system is not only of advantage to man, but is the means of detecting and preventing disease among cattle, sheep, and swine. A sharp outlook at the slaughter house will discover the first appearance of rinderpest, foot-and-mouth disease, Texas fever, or other epizootic, which may then be quickly traced to its origin and nipped in the bud. Foci of herd diseases, such as tuberculosis, actinomycosis, and hog cholera may thus be located. A meat inspection service is therefore of great economic importance and an effective agency in eradicating dangerous diseases from the food herds of the country.

The border line between health and disease is ill-defined. It is doubtful whether any animal slaughtered for food is wholly sound. Parasitic infections among the lower animals are exceedingly common. Anyone may convince himself of this fact by a visit to a slaughter house, for there he will see that many hogs have a handful of round worms in the intestinal tract; most animals have one or more species of intestinal worms, such as hookworms, tapeworms, and many protozoa, but, fortunately, these are for the most part not dangerous to man. Almost every hog or beef that is killed contains *Sarcosporidia*, small parasites that inhabit the muscles of these animals; they are harmless to man. Meat inspection aims to eliminate those diseases which are injurious to man and those diseases and conditions which render the meat of inferior quality or otherwise unfit for use. In establishing correct principles to guide a meat inspection service sentiment must give way to science. The killing of animals and dressing of the carcasses is not a kid-glove business. It involves more or less blood and dirt. In our country much good meat has been condemned and destroyed according to law as a result of supersensitiveness. As meat becomes scarcer and prices higher, this waste will be checked by closer adherence to a sound application of pathology.

The practices of meat inspection vary in different countries, depending upon the local conditions. Thus, in some countries, which have long had a scarcity of meat, and the people are, therefore, flesh hungry, much meat is passed for food that would here be condemned. In countries where meat is not very abundant it is even necessary for the

officials to keep a sharp watch to prevent the people from eating meat known to be injurious. In America the attitude is very different, for we have a repugnance even against meat known to contain a harmless parasite. The need of conservation, especially since the World War, has placed our meat inspection service on a more practical basis, without sacrificing good standards.

The Federal Meat Inspection System depends for its authority upon the interstate and foreign commerce clause of the Constitution of the United States, and this inspection is therefore limited to the products of establishments that are engaged in interstate or foreign commerce. The Federal Government is powerless to exercise any supervision over an establishment, the meat of which is slaughtered, prepared, sold and consumed entirely within a single state. It is therefore the duty of each state or municipality to supplement the Federal Inspection Service with an efficient local inspection system to cover the intra-state supply.

A meat inspection service should have for its object first of all the protection of the consumer against diseased or other injurious qualities contained in the meat. This should be accomplished with as little waste of food products as practicable, and, finally, the meat should be honestly labeled so that the consumer may know just what he is buying.

**The Abattoir.**—So long as animals are permitted to be slaughtered in any barn or cellar it is impossible to exercise a proper control over meat and meat products, and conditions which endanger the public health will prevail. The first essential of a good meat inspection service is to concentrate all slaughtering in large central sanitary abattoirs. This simplifies the inspection and sanitary control, and is a needed measure to protect the consumer. In Germany and England public abattoirs have been established which belong to the city. These structures are built thoroughly of brick and concrete and are well protected against rats. They are situated near a railroad, so as to facilitate transportation, and are so constructed that they may be kept clean. Each person who wishes to slaughter must obtain a permit and pay rent. In the entire city of Paris there are only three slaughter houses. The erection and maintenance of well controlled, modern slaughter houses is one of the needs of our country, especially in the smaller towns, and until this reform is accomplished we shall never have a satisfactory solution of the meat problem.

An abattoir must be especially well constructed and kept clean. The same may be said of the trucks, drays, and all objects that come in contact with the meat. Slaughtering and butchering involves more or less blood and dirt, hence the necessity of frequent and repeated cleaning. The water-closets, toilet rooms, and dressing rooms should be entirely separated from the departments in which the carcasses are dressed or meat products handled or prepared. Attention must be paid to

eliminate all sources of odor that may contaminate the meat, and every effort must be made to keep out flies and other vermin, especially rats and mice. Dogs should not be allowed around slaughter houses on account of the danger of spreading the echinococcus and other parasites. The feeding of hogs on the uncooked refuse of slaughter houses should not be permitted.

The employees themselves must be cleanly and should wear clean outer clothes that may be readily laundered. The federal regulations even prescribe that employees shall pay particular attention to the cleanliness of their boots and shoes. It is just as important to wash the hands before beginning work, and to be particular after each visit to the toilet in the slaughter house or butcher shops, as it is in the milk industry. Persons with tuberculosis or other communicable disease should not be permitted in any department of the work where the meat or meat products are handled or prepared in any way. It is important that butchers who handle a diseased carcass should thoroughly cleanse their hands of all grease and then immerse them in a good disinfecting solution. Butchers' implements used on diseased carcasses should be sterilized in boiling water or strong carbolic acid or formalin solution and thoroughly cleansed before they are again used. The federal meat inspectors are required to furnish their own implements for their own dissection or examination of diseased carcasses or unsound parts. The precautions required in an abattoir and butcher shop are based on the same principles as those in a surgical clinic. Meat that falls upon the floor or otherwise becomes soiled is required to be removed and condemned. Inflation by air from the mouth should not be permitted, inflation by mechanical means is also prohibited by the Department of Agriculture. Only good, clean, and wholesome water and ice should be used in the preparation of the carcasses, and the wagons and cars and all surfaces with which the meat comes in contact should be kept clean and in good sanitary condition. There is no objection to the use of the skin and hoofs of animals condemned on account of tuberculosis and other diseases (except anthrax) communicable to man, provided they are disinfected. Each skin and hide must be immersed for not less than five minutes in a 5 per cent. solution of liquor cresolis compositis or a 5 per cent. solution of carbolic acid or a 1-1,000 solution of bichlorid of mercury.

Every complete abattoir must be provided with a retaining room or place, a condemned room, and a tank room. The retaining room or place is set apart for the final inspection of all carcasses and parts which the inspector desires to examine more carefully at his leisure. The retaining room must be large enough to have carcasses hang separately, furnished with abundant light, and provided with sanitary tables and other necessary apparatus. The condemned room must be securely rat-proof and be under the lock and seal of the inspector. The object of

this room is to contain all carcasses and parts of carcasses until they can be tanked or disposed of in accordance with instructions.

All condemned carcasses or parts of carcasses are tanked under special requirements in an official abattoir. Tanking consists in exposing the carcasses to steam under a pressure of not less than 40 pounds, having a temperature of 288° F., and maintained not less than six hours. This effectively renders the contents of the tank unfit for food purposes. In the absence of tanking facilities the condemned meat may be slashed with a knife and then denatured with crude carbolic acid, kerosene, or other agent, when it may be removed to some other establishment having proper tanking facilities.

**Qualifications of a Meat Inspector.**—A corps of thoroughly trained meat inspectors is one of the most important links in the chain of an efficient meat inspection system. A meat inspector should be a qualified veterinarian having special experience and training for his specialty. He must know the anatomy of the various food-producing animals, especially cattle, horses, swine, sheep, and also fowl, and must be acquainted with the normal parts of each. He must be able to distinguish between the various organs of the various species, so that he cannot be imposed upon by those who would like to substitute one for another. He must know how to examine animals during life, in order to determine whether they are healthy. He must know the character of all the infectious diseases which are likely to pass through the district where he is situated. The government recognizes that it requires a high degree of skill to conduct this work, and it has, therefore, placed the meat inspection service under the Civil Service, and, further, will admit veterinarians only if graduates of recognized veterinary colleges. In addition they are required to pass a Civil Service examination.<sup>5</sup>

**The Freibank or Three-Class Meat System.**—In Germany and certain other European countries meats are divided into three classes, viz., a first class, including meats which are passed for unrestricted trade; a second class, or *Freibank* meats, which are allowed on the market under certain restrictions; and a third class, meats which are condemned and thus excluded from the food supply.

The federal meat inspection system of our country has been a two-class meat system, that is, meats coming to inspection are either passed for unrestricted trade or they are condemned and thus excluded from use as a food. However, a third class was recognized during the World War, and the amount of such meat passed after it is sterilized by steam now carries us well towards the three-class system.

The following carcasses or parts of carcasses may be rendered into

<sup>5</sup> There is also a large force of "Lay Inspectors" experienced in curing, canning, packing and otherwise preparing of meats and experienced in the inspection of products.

lard or tallow or passed for food after sterilization, provided the disease is moderate and limited, and then only after the lesions and surrounding parts are removed and condemned: *Cysticercus bovis* (beef tape worm); *cysticercus cellulosae* in hogs; *cysticercus ovis* in sheep; caseous lymphadenitis; tuberculosis; hog cholera and swine plague; icterus, if not the result of infection or intoxication and provided discoloration disappears on chilling; advanced pregnancy showing signs of parturition, also carcasses showing signs of having given birth to young within 10 days, and in which there is no evidence of septic infection. (See Bureau Animal Industry Order 211.) Any of the above must be plainly labeled to show that the product is second-class grade or quality. The carcass or the part, as well as the can or container, must be plainly and conspicuously labeled "PREPARED FROM MEAT PASSED FOR STERILIZATION."

The system of the German *Freibank* and the compulsory declaration of the condition of inferior meats are very old. The municipal laws of Augsburg as long ago as 1276 prescribed that inferior meat could not be sold without giving notice as to its quality. In 1404 the municipal laws of Wimpfen provided that the *Freibank* (from the German *frei*, free, here in the sense of unconnected or separate, and *bank*, a counter or stall) should be situated three paces away from the regular counters. The *Freibank* is, therefore, a counter which is free or separate from the counters on which the first class meats are sold. The term "*Finnenbank*" is sometimes used for these special meat stalls because measly meat or "*finneges Fleisch*" especially is sold at these places. This system of the *Freibank* has been extended quite generally in Germany and is rapidly extending in France, Belgium, Italy, and other European countries. Meat from tuberculous animals, from animals containing cysticerci (the larval stage of tapeworms), trichinous meat, and meat that would otherwise be injurious if eaten raw, but is entirely safe as far as these infections are concerned when thoroughly cooked, is first sterilized by steam before it is placed upon the *Freibank*. It has been the more or less general experience that the introduction of the *Freibank* system has at first been met with by prejudice from various sides, but it is also the experience that this prejudice gradually wears off, and that in some places the demand for this meat becomes greater than the supply. In any event, no large quantity of such meat should be sold to any one purchaser, so as to prevent its being used to any great extent in boarding houses and restaurants.

**Emergency Slaughter.**—In Germany the system known as emergency slaughter or *Nothschlachtung* has developed to large proportions. Animals that are sick or injured are killed, examined, and, if suitable for food, are labeled, inspected, and passed. In this way much valuable foodstuff is saved that would otherwise be lost. It is said that over

1 per cent. of the animals killed for food in Germany come under this emergency rule. The meat of animals killed under the emergency laws is so labeled and sold as second quality. There is also a certain amount of what may be termed emergency slaughter going on in the local uninspected slaughter houses of America, but it is not countenanced by law, and is, therefore, done in secrecy. Since 1914 emergency slaughter has been permitted under our Federal Meat Inspection Service, subject, however, to carefully stated restrictions.

**Methods of Slaughter.**—In slaughtering, the principal indications are: (1) a sudden and painless death; (2) an immediate withdrawal of the blood; (3) removal of intestines and hair or hide; (4) immediate cooling. Animals should be kept without food for at least 12 hours before slaughter. Sheep and hogs are usually hung by the hind feet and the large vessels of the neck dexterously cut with a sharp knife and with a single motion of the hand. Cattle are usually first stunned by a blow upon the head, then hung up by the hind legs and bled.

The Jewish method of slaughtering is regarded by many as superior to any other. It consists in cutting all the large vessels of the neck with one cut of a long, keen knife. The method is part of a ritual which includes an inspection of the animal and its organs for evidence of disease, according to the Mosaic laws. This is the oldest system of meat inspection. According to Dembo<sup>6</sup> it is the most rational from a hygienic standpoint, since the animal is bled rapidly and completely, and the convulsive movements cause the meat to be more tender and of more attractive appearance. Rigor mortis comes on more quickly, and the meat is, therefore, more quickly available for use, and also will keep several days longer than ordinarily.

A process of slaughtering originating in Denmark appears to have borne the test of trial in a very satisfactory manner, and recommends itself for adoption in the tropics, where meats decompose with exceeding rapidity. The animal is shot in the forehead and killed, or stunned, and as it falls an incision is made over the heart and the ventricle is opened for two purposes: to allow the blood to escape and to admit of the injection of a solution of salt through the blood vessels by the aid of a powerful syringe. The process requires but a few minutes, and the carcass may be cut up at once.

The common methods of killing fowl intended for the market are either by bleeding, by dislocation of the neck, or by chopping off the head. When the neck is stretched and dislocated the skin remains unbroken and no bruised effect is produced, but most of the blood in the body drains into the neck and remains there. In killing a fowl by bleeding the common procedure is to string it up by the legs with the head

<sup>6</sup> *Deutsche Vierteljahresschrift für öffentliche Gesundheitspflege*, XXVI, p. 688.

hanging downward. The operator then gives it a sharp blow with a stick on the back of the head, and when he has stunned it by this means he inserts a sharp knife into the roof of the mouth, penetrating the brain. He also severs the large vessels of the throat by rotating the knife, and the bird rapidly bleeds to death.

**The United States Meat Inspection Law.**—The Federal Meat Inspection Law, approved June 30, 1906, provides for the inspection of cattle, sheep, goats, and swine, the meats or meat food products, which are to enter into interstate or export trade. It is administered by the Bureau of Animal Industry under the direction of the Secretary of Agriculture. It should be remembered that the Federal Meat Inspection Law applies only to meat and meat products sold in interstate commerce or for export trade, and does not apply to meats butchered, dressed, and sold within the state. In accordance with our dual form of government, the inspection of meat that is slaughtered, dressed, and sold within the borders of a single state is left entirely to the authority of that state. It is not until some of this meat passes the state line that it enters interstate traffic and comes under the provisions of the federal law. Some of the states have passed laws similar to the federal law to protect their own citizens. In this way a more or less uniform method of meat inspection is gradually extending throughout the country.

The Federal Meat Inspection Law provides for inspection of animals before and after they are slaughtered; also inspection of all the meat and products processed, prepared or stored in the plant. It exercises supervision and control in respect to the kinds of preservatives used and over the marking and labeling of products, including the special marking of carcasses and meats which are held for further inspection, and of those condemned. Custody is maintained of all condemned carcasses and products, and their destruction supervised. Regulations for the maintenance of sanitary condition throughout the plant and for the cleanly handling of meats and products are prescribed and enforced. The regulations prescribe an inspection substantially the same for meats which are imported.<sup>7</sup>

**Ante-mortem Inspection.**—A careful ante-mortem examination or at least an inspection of all cattle, sheep, swine, goats, etc., about to be slaughtered should be made by a competent veterinarian. Any animal showing symptoms of or suspected of being infected with a disease or condition which would probably cause its condemnation when slaughtered should be set aside. These animals should then be slaughtered separately in a place provided for this special purpose. If necessary the temperature of the animal may be taken in the ante-mortem examination, although due allowance must be made for rise in temperature due

<sup>7</sup> Nevertheless an immense amount of meat slaughtered, shipped, sold and consumed wholly within a single state comes under Federal inspection.

to excitement and undue exertion, especially in hogs. Animals commonly termed "downers" or crippled animals are set aside and slaughtered separately.

**Post-mortem Inspection.**—The post-mortem inspection is nothing more or less than a well-conducted autopsy. The head, tongue, tail, thymus gland, and all viscera, and also the blood and all parts used in the preparation of food and medicinal products should be retained in such a manner as to preserve their identity until the post-mortem examination is completed. It is, of course, impracticable to formulate rules to cover all conditions and diseases, and much must, therefore, be left to the judgment, experience, and training of the veterinary inspector in charge. Carcasses or parts of carcasses with the following diseases or conditions are condemned, depending upon circumstances: anthrax, pyemia and septicemia, vaccinia, rabies, tetanus, malignant epizootic catarrh, hog cholera and swine plague, actinomycosis, caseous lymphadenitis, tuberculosis, Texas fever, parasitic icterus, hematuria, mange or scab, trichinosis, tapeworms, infections that may cause meat poisoning, icterus, uremia, and sexual odor, urticaria, melanosis, tumors, bruises, abscesses, liver flukes, and other parasites, emaciation from anemia, immaturity, milk fever, and railroad sickness. A few of these diseases deserve brief mention.

**Tuberculosis.**—Tuberculosis is exceedingly common in cattle and is becoming more and more prevalent among hogs. A preponderating percentage of all carcasses condemned as unfit for food is so condemned on account of tuberculosis. Thus, under Federal meat inspection, 40,792 cattle, or 0.372 per cent., and 59,740 swine, or 0.168 per cent., were condemned on account of tuberculosis in the fiscal year 1918. In the same year 10,586 cattle and 88,915 swine affected with localized or limited tuberculosis were passed for sterilization after removal of all affected parts. Tuberculosis is important, not alone because so many food animals are infected with it, but because it presents a peculiarly difficult problem for the meat inspector. The fundamental thought in determining whether to pass or condemn meat of a tuberculous animal is that it should not contain tubercle bacilli, and should not be impregnated with toxic substances of tuberculosis or associated with septic infection. If the lesions are localized and not numerous, if there is no evidence of distribution of tubercle bacilli throughout the blood, and if the animals are well nourished and in good condition, there is no reason to suspect that the flesh is unwholesome, and it is permitted to be used after the removal of the infected portions. Just when tuberculosis should be considered localized or generalized, from the standpoint of meat inspection, is frequently a difficult question to determine. Fortunately, the danger from this source is not very great, as tuberculosis of muscle is exceedingly rare, and the further safeguard of cooking is

sufficient to kill the tubercle bacilli, provided the meat is thoroughly cooked throughout. The relation of bovine tuberculosis to human tuberculosis has been discussed on page 166.

Tuberculosis of cattle shows itself in four primary lesions: (1) the retropharyngeal lymph nodes, (2) the lungs and associated lymph nodes, (3) the mesenteric lymph nodes, and (4) the liver. From the retropharyngeal nodes the process extends to the cervical lymph nodes and also to the anterior mediastinal lymph nodes. When this group of glands alone is infected the disease may be considered as localized. From the mesenteric lymph nodes the infection frequently reaches the peritoneum, and from the bronchial lymph nodes the pleura. The newly formed growth in the peritoneal or pleural cavities may be enormous in amount. It is often suspended from the omentum in great grape-like masses (*Perlsucht*), or the intestines may be plastered with tubercles. In these cases the animal otherwise may be in good condition; that is, the disease is still outside the vital organs and the tubercle bacilli have not invaded the blood stream. In Germany it is permitted to cut off such growth and allow the meat to go into consumption. In our country the meat of such animals is rejected.

For practical purposes it is necessary to formulate definite rules for the guidance of the veterinary inspector, and this is done with minute particularity in the regulations of the Bureau of Animal Industry in the case of tuberculosis. In general, if the tuberculous lesions are limited to a single part or organ of the body without evidence of recent invasion of tubercle bacilli into the general circulation, the diseased parts are removed and the remainder of the carcass is passed for use. If the animal suffered from fever before it was killed or is cachectic, anemic, and emaciated, or if the lesions are generalized, especially if they exist in two or more body cavities, or if the lesions are found in the muscles, intermuscular tissues, bones, or joints, or if the lesions are multiple, acute, and actively progressive, the carcass is condemned. Carcasses which reveal lesions more severe or more numerous than those described for carcasses to be passed, but not so severe or numerous as the lesions described for carcasses to be condemned, may be rendered into lard or tallow or otherwise sterilized in accordance with the regulations, when the distribution of lesions is such that all parts containing tuberculous lesions can be removed.

*Anthrax*.—All carcasses showing lesions of anthrax, regardless of the extent of the disease, are condemned and immediately incinerated. This includes the hide, hoofs, horns, viscera, fat, blood, and all portions of the animal. The killing bed upon which the animal was slaughtered must then be disinfected with a 10 per cent. solution of formalin, and all knives, saws, and other instruments that have come in contact with the infection must be boiled or otherwise disinfected.

*Hog Cholera and Swine Plague.*—Carcasses showing well-marked and progressive lesions of these diseases in any organ or tissue are condemned. If the lesions are slight and limited they may be passed for sterilization. Man is not susceptible to hog cholera.

*Actinomycosis.*—If the animal is in a well-nourished condition and the disease has not extended from a primary area of infection in the head, the head, including the tongue, is condemned and the remaining part of the carcass may be used, but if the disease is generalized the entire carcass is considered unfit for human use and condemned.

*Tapeworm Cysts.*—Carcasses of animals affected with tapeworm cysts, known as *Cysticercus bovis*, are condemned if the infestation is excessive or if the meat is watery or discolored. Carcasses showing a slight infestation may be passed for food after removal and condemnation of the cysts, provided the carcasses are then held in cold storage or pickle for not less than 21 days; the time in storage may be reduced to 6 days if the temperature does not exceed 15° F. Calves under 6 weeks old are not subject to *Cysticercus bovis*. As an alternative to retention in cold storage or pickle, such carcasses may be passed for sterilization.

Carcasses or parts of carcasses found infected with hydatid cysts (*echinococcus*) may be passed after condemnation of the infected part or organ.

*Septic and Pyemic Conditions.*—All carcasses of animals so infected that consumption of the meat or meat food products thereof may give rise to meat poisoning should be condemned. For the information of the inspector the following conditions are specified: (1) acute inflammation of the lungs, pleura, peritoneum, pericardium, or meninges; (2) septicemia or pyemia, whether puerperal or traumatic or without any evident cause; (3) severe hemorrhagic or gangrenous enteritis or gastritis; (4) acute diffuse metritis or mammitis; (5) polyarthrititis; (6) phlebitis of the umbilical veins; (7) traumatic pericarditis; (8) any other inflammation, abscess, or suppurating sore if associated with acute nephritis, fatty and degenerated liver, swollen soft spleen, marked pulmonary hyperemia, general swelling of the lymphatic glands, and diffuse redness of the skin, either singly or in combination.

It is required that, immediately after the slaughter of any animal so diseased as to require its condemnation, the premises and implements used must be thoroughly disinfected. The part of any carcass coming in contact with the carcass of any diseased animal or with the place where such animal was slaughtered, or with the implements used in the slaughter, before thorough disinfection has been accomplished, should also be condemned.

*Meat poisoning* is not a poisoning at all, but an acute infection, caused in the majority of cases by *B. enteritidis* or closely allied bacillus

*Diseases and conditions for which condemnations were made on post-mortem inspection, fiscal year 1917*

\* Regulations of the Bureau of Animal Industry, Department of Agriculture. A Condensed Epitome of the Principles and Practice of Meat Inspection.

EDLEMANN: "Meat Hygiene." Translated by Mohler and Eichhorn, Lea & Febiger, 1911; 4th edition, 1919.

OSTERTAG: "Handbuch der Fleischschau." Stuttgart, 8th Edition, 1914.

in the colon-typhoid group. The subject is fully discussed on page 692.

The food an animal eats produces distinctive odors or tastes in its flesh. Poisonous substances ingested by an animal may be deposited in its tissues in amounts sufficient to be poisonous to man. Chickens may be accustomed to strychnin in such large amounts that this method is used in the south to kill the hawks that prey upon them.

*Partridge poisoning*, which was apparently quite common in the first

half of the eighteenth century, was probably due to mountain laurel (*Kalmia latifolia*), which is eaten by grouse in the winter time. The poisonous principle is known as andromedotoxin, and Chestnut was able to show that partridges may eat enough of the laurel with impunity to themselves to render their flesh poisonous.

**Miscellaneous.**—In addition to the infections noted, the following diseases are sometimes transferred from the flesh or organs of lower animals, or by contact with the lower animals in various ways: tuberculosis, anthrax, glanders, rabies, actinomycosis, foot-and-mouth disease, cowpox, ringworm, and various pyogenic and septic infections.

Meat may occasionally be injurious to health from a variety of miscellaneous causes. Thus, an animal that has died of arsenic or other poisonous substance may contain sufficient of the poison in the tissues to affect the person who eats part of the flesh.

The belief that sickness in man can follow the consumption of the flesh or milk of animals which have previously fed upon poisonous plants is not unfounded. Chestnut<sup>8</sup> states that as much as three grains per liter of formic acid may be present in honey, and that poisons from various plants have been isolated from honey. Pammel<sup>9</sup> furthermore states that garlic, chicory, cabbage or turnips, when eaten by cows, impart a bad taste to the milk and cites instances of poisoning in man and animal due to ingestion of the milk from animals which had eaten *colchicum*, *mandrake*, and the death camas (*Zygadenus venenosus*).

### ANIMAL PARASITES

**Trichinosis.**—*Trichinella spiralis*, formerly *Trichina spiralis*, commonly known as trichina, is a round worm which passes its entire life cycle in man, rat, or hog. Many other animals, such as mice, foxes, guinea-pigs, rabbits, cats, dogs, etc., are susceptible. This parasite differs from many other animal parasites in affecting several genera and in passing its entire life cycle in each host. Trichinosis is rare in animals which do not eat meat.

Trichiniasis (usually called trichinosis) is not a mere medical curiosity. It is a common and important disease, readily preventable. The average mortality is about half that of typhoid fever, in some epidemics, however, rising to 16 or even 30 per cent., as in the Hedersleben epidemic<sup>10</sup> in 1865. The parasites are found in from 0.5 to 2 per cent. of all necropsy subjects.<sup>11</sup> About 1 to 2 per cent. of American swine and a larger per cent. of American rats are infected.

<sup>8</sup> *Science*, XV, 1902, 1016.

<sup>9</sup> *Manual of Poisonous Plants*, Vol. I, p. 65.

<sup>10</sup> Cited by Stäubli, *Trichinosis*, Wiesbaden, 1909, p. 16.

<sup>11</sup> Williams found evidence of infection in 5.3 per cent. of 505 consecutive autopsies in Buffalo, N. Y.

The larvae are imbedded in the muscles. When the trichinous meat is taken the capsules are dissolved in the stomach, the larvae set free; the freed larvae enter the intestine, where they find conditions favorable, and where in about two days they grow into the full mature worm. The female produces upward of five hundred young, and as she is partially imbedded in the wall of the intestine is able to deposit her embryos directly in the lymph spaces in the intestinal mucosa. The embryos get into the blood stream and are thus distributed to the muscles. They may be found in large numbers in the circulating blood, between the eighth and twenty-fifth days after infection. After settling down in the muscles, the young parasites increase rapidly in size, reaching a length of about 1 mm., assume their characteristic spiral form, and become encysted, the formation of the cyst beginning about a month after infection. The adult worms usually disappear from the intestines in 5 or 6 weeks, or even sooner if the patient has diarrhea. Calcification of the capsules surrounding the encysted larvae in the muscles may begin as early as six months after infection. The parasites may remain alive for many years in calcified capsules, but sooner or later if the host remains alive the parasites die or are absorbed or themselves become calcified.

FIG. 82.—*TRICHINELLA SPIRALIS*.  
Entire Life Cycle in Each Host.

Some authorities consider rats to be the normal or common host of *Trichinella spiralis*, others believe that the hog is the only important reservoir of the parasite, and that in the absence of hogs the parasite would be unable to perpetuate itself among rats. It is a well known fact that rats about slaughter houses and butcher shops are commonly infested with trichinae, and though it is questionable to what extent rats are responsible for the spread of infection to hogs, the possibility of their importance in this respect cannot be disregarded. Clearly important sources of infection for hogs are the carcasses of dead hogs, offal from slaughter houses, and refuse or garbage containing pork scraps. (Infection through feces has never been proved, and it is quite unusual if it ever occurs.) Man receives the infection by eating trichinous pork (occasionally dog, cat, or bear meat). The country slaughter houses, where hogs are fed on human feces and the offal of slaughtered animals and where rats abound, are the most important factors in the propagation of the infection.

Not all persons who eat trichinous flesh have the disease. A limited

number of the embryos do not cause noticeable symptoms. The number of encysted larvae that may be present in severe infestations is very large. As many as 1,200 have been counted in a piece of muscle weighing 1 gram, which would make about 500,000 in a pound. The number of encysted larvae present in the bodies of persons who have died from trichinosis has been estimated, in various cases, at from 5,000,000 to 100,000,000. The severity of the disease depends upon the number of live embryos swallowed. In man the disease is well characterized in two stages: (1) gastro-intestinal, (2) general infection. The symptoms of the second stage are fever,<sup>12</sup> intense pain in the muscles caused by the migration of the parasites, edema, and leukocytosis. The count of the white cells may reach 30,000 with distinct eosinophilia. One attack of trichinosis does not confer an immunity. Schwartz<sup>13</sup> has shown that experimental animals infected and harboring trichinae in their muscles are not immune to further infection when fed trichinous meat.

The recognition of trichinosis as a distinct infection is recent (1860). The parasite was named by Richard Owen (1835) and was long regarded as harmless and as a curiosity. The infection was mistaken for typhoid fever, rheumatism, acute miliary tuberculosis, and other diseases of common occurrence. The particular case which finally revealed the parasite as being capable of harm was that of a young woman admitted to the hospital at Dresden suffering from a disease diagnosed as typhoid fever. The patient had agonizing pains in the muscles, and the autopsy revealed the parasite imbedded in vast numbers in the muscular fibers. Leidy in 1846 had announced the discovery of trichinae in pork and in the present case an investigation included the examination of some pork of which the patient had eaten four days before the first symptoms appeared, with the result that the same parasites were found. Since then many local outbreaks have been described, more particularly in Germany, where the custom prevails of eating raw or underdone pork, especially in sausage.

As an indication of the prevalence of trichinae it may be noted that microscopists of the U. S. Department of Agriculture found living trichinae in 115,812 hogs out of 8,257,928 examined during the period 1898-1906, or 1.41 per cent., from which it would appear that from 1 to 2 per cent. of the hogs in this country are trichinous. The disease in man is probably more prevalent than the figures of the clinicians indicate. Careful search at autopsy showed that many persons have been infected but have recovered. Thus, Williams,<sup>14</sup> of Buffalo, examined 505 cadavers (largely from almshouses and insane hospitals so his material cannot be considered to represent a fair average of the population)

<sup>12</sup> *Trichinella spiralis* is the only metazoic parasite that, infecting man, causes fever with constancy.

<sup>13</sup> *J. A. M. A.*, Sept. 15, 1917.

<sup>14</sup> *Journal Medical Research*, July, 1901, VI, No. 1, p. 64.

and found the parasites present in 27, or 5.34 per cent. Osler states that about one-half to two per cent. of all bodies at autopsy contain trichinae.

*Prevention.*—The disease is practically never recognized in swine during life. The protection rendered by the inspection of meat is quite unsatisfactory. This inspection consists in compressing small fragments of the muscle (diaphragm, tongue, etc.) between two glass plates, which are then examined with a low power of the microscope for the encysted larvae. That this examination is not an entirely satisfactory safeguard, even in cases where it is done with care and precision, is shown by the fact that in Germany, for example, the disease is still very common. Of the 6,329 cases of trichinosis occurring in Germany between 1881 and 1898, over 32 per cent. (2,042 cases) were traced by Stiles to meat which had been inspected and passed as free from trichinae. The microscopic inspection of every carcass for trichina is expensive and open to several practical sources of error. It, therefore, gives a false sense of security and is impractical in country slaughter houses.

Our federal meat inspection regulations no longer require a microscopic examination of pork for trichina. Until recently all the pork dressed for export was examined by the microscopic method, but this has also been discontinued.

The U. S. Bureau of Animal Industry issues the following warning:

"No method of inspection has yet been devised by which the presence or absence of trichinae in pork can be determined with certainty, and the Government meat inspection does not include inspection for this parasite. All persons are accordingly warned not to eat pork, or sausage containing pork, whether it has been officially inspected or not, until after it has been properly cooked.

"A temperature of about 160° F. kills the parasite, therefore pork when properly cooked may be eaten without danger of infection. Fresh pork should be cooked until it becomes white and is no longer red in color in all portions of the piece, at the center as well as near the surface. Dry-salt pork, pickled pork, and smoked pork previously salted or pickled, provided the curing is thorough, are practically safe so far as trichinosis is concerned, but as the thoroughness of the curing is not always certain, such meat should also be cooked before it is eaten."

The trichinae are not particularly resistant. The thermal death point of trichina larvae is 55° C.<sup>15</sup> As a factor of safety, the Bureau of Animal Industry requires 137° F. (58.33° C.) as the minimum temperature to which pork and products containing pork are required to be heated when cooked in establishments operating under Federal

<sup>15</sup> Ransom and Schwartz: *Journ. Agric. Research*, XVII, 5, Aug. 15, 1919. Ransom, B. H., Schwartz, B., and Raffensberger, H. B.: Effects of Pork-Curing Processes on Trichinae. *Bull. No. 880, U. S. Dept. of Agriculture*, Sept. 10, 1920.

meat inspection. The requirement refers to the temperature actually reached in the interior of the meat (pages 695 and 750).

*Trichina* larvae die in less than 20 days at a temperature not higher than 5° F. Ransom<sup>16</sup> disproved the notion formerly held that the larvae of *Trichinella spiralis* are very resistant to cold. He recommends that meat should be refrigerated at a temperature not higher than 5° F. for not less than 20 days, a period which allows a probable margin of safety of 10 days. Whether temperatures higher than 5° F. may be safely employed by lengthening the period of refrigeration, remains to be determined. It is, therefore, evident that refrigeration and time are better safeguards than microscopic examination, although there are

various practical difficulties to a universal refrigeration of pork at the low temperature required to kill trichinae. The combination of refrigeration and thorough cooking would protect man against trichinosis.

FIG. 83.—*TAENIA SOLIUM*, THE PORK OR MEASLY TAPEWORM.

Note that man may infect himself.

The rat and the hog should be regarded as the common reservoir of trichinae;

a persistent warfare should be made against rats in slaughter houses, butcher shops, markets, and places where hogs are kept (see page 328). Hogs should not be fed uncooked offal from slaughter houses, and on the farms should not be allowed to eat the carcasses of dead hogs.

**The Pork or Measly Tapeworm (*Taenia Solium*).**—*Taenia solium* passes the larval stage of its life history in the flesh of pork. These encysted larvae are known as bladder worms or *Cysticercus cellulosae*; they are commonly called pork measles. Man eats these encysted larvae which develop into adult tapeworms in the intestinal tract.

Infection with this tapeworm may be particularly dangerous, because the cysticerci may occur in man as well as in the hog. When the cysticerci develop in important parts, such as the eye, brain, etc., death or serious consequences may ensue. The infection with this particular tapeworm is fortunately rare in the United States and Canada, but is more frequently met with in the old world. The adult tapeworm occurs only in man; the larva is found especially in hogs and occasionally in

<sup>16</sup> *Science*, New York, January 30, 1914, Vol. XXXIX, p. 181, and *The Journal of Agricultural Research*, Vol. V, No. 18, January 31, 1916.

man. This parasite is smaller than the beef tapeworm. The head is armed with a double row of hooks, with which it maintains its hold to the mucous membrane. Each link contains a uterus with lateral branches, and the genital pore is marginal and irregularly alternate.

The source of infection in man is practically always the larvae in undercooked or raw pork. Occasionally the cysticerci develop in man; in this case, the infection is contracted from another person through the eggs in the feces. Auto-infection also occurs. Hogs become infected from eating human feces containing the eggs, or from food and drink contaminated with them. To build a privy over the pig pen, as one sometimes sees in the country, means the formation of an endless chain in the biology of this worm.

*Taenia solium* produces less anemia than the fish tapeworm (*Dibothriocephalus latus*), but may be dangerous because of cysticercus formation in man. This is the only tapeworm in which this occurs. A person infected with *Taenia solium* may reinfect himself through dirty finger nails, unwashed hands, or other uncleanly habits, and it is also comparatively easy to infect others through the feces.

In prevention one must first consider the disposal of feces. Hogs heavily infected should be destroyed; those having a light infection may be thoroughly cooked and the meat eaten. As the larvae of *Taenia solium* appear to be more tenacious of life than those of *Taenia saginata* and survive longer after the death of their host, the holding of meat for a period of 21 days in refrigeration or in brine as practiced in the case of beef slightly infested with *Taenia saginata* larvae is a method that cannot be utilized for destroying vitality of the larvae of *Taenia solium* in pork.

**Taenia Saginata.**—*Taenia saginata*, also called *T. mediocanellata*, occurs only in cattle and man. The tapeworm is rather common in our country, but is not dangerous, like *Taenia solium*, though at times it produces a certain degree of anemia and other symptoms. It is often difficult to expel, despite the fact that it has no hooks. In geographical distribution it is cosmopolitan. The adult worm occurs in man; the larva is found imbedded in beef and is known as the *Cysticercus bovis*. The uterus has 15 to 35 slender dichotomous branches on each side. The genital pore is marginal and irregularly alternate.

Ransom<sup>17</sup> concludes that if measly beef carcasses are exposed 6 days to a temperature not exceeding 15° F. the parasites die. Ostertag,<sup>18</sup> also Ransom, have found that cysticerci from beef carcasses held in cold storage or in pickle for 21 days are no longer viable.

Man becomes infected by eating raw or underdone beef. The larvae are most frequently detected in the heart, diaphragm, and muscles of

<sup>17</sup> *Jour. of Parasitology*, Sept. 1, 1914, No. 1.

<sup>18</sup> *Zeitschr. f. Fleisch. u. Milchhyg.*, v. 7, pp. 127-132, 1897.

mastication, but occur throughout the voluntary musculature. Cattle become infected through the eggs passed in human feces, which contaminate their food or water.

*Prevention.*—The prevention depends first upon proper disposal of human excrement and an efficient system of meat inspection. The cysticerci die in three weeks after killing, hence meat that has been preserved 21 days may be regarded as safe. Proper cooking and thorough salting also kill the larvae of this tapeworm.

**Echinococcus Disease.**<sup>19</sup>—The larvae of a cestode, *Taenia echinococcus*, frequently infests man. The larvae are hydatids of a minute tapeworm of the dog. The adult worm in the intestinal tract of the dog is not

FIG. 84.—BEEF TAPEWORM.

more than four or five millimeters long and consists of three or four segments of which the terminal one alone is mature. The head is small and provided with four sucking disks, and a rostellum with a double row of hooklets. The terminal or mature segment contains about 5,000 eggs. The eggs are passed in the feces and then infest various animals, particularly the hog and ox, more rarely the horse and sheep. The egg hatches in the digestive tube, liberating an embryo which pierces the mucosa and lodges in

the various tissues and organs of the body, where it develops into the larval or cystic stage (hydatids).

The disease prevails especially in those countries where man is brought in close contact with the dog, but more especially when, as in Australia, the dogs are used to herd sheep. The dog gets the larvae from the sheep. In the dog the tapeworm reaches maturity in the intestinal canal, and the eggs are passed in the feces to infect sheep, man, and other animals. In this country *Taenia echinococcus* is rarely found in the dog, but it is not a very rare parasite, as its cystic stage is rather frequently encountered in the liver of hogs by Federal meat inspectors. The larva imbeds itself in the tissues and there develops a cyst—the hydatid cyst. This may occur in the liver, lungs, abdominal organs, nervous system, in fact in almost any part of the body. The cysts grow in size as the larvae multiply, forming daughter cysts and grand-daughter cysts.

The first essential in prophylaxis is to protect the dog against infection. This resolves itself into a good system of meat inspection, sanitary slaughter houses, proper disposal of offal, and the keeping of dogs

<sup>19</sup> Echinococcus disease is not contracted by man from meat—but is conveniently considered in this chapter with the other tapeworms.

away from slaughter houses, butcher shops, rendering plants, and the like. If offal is used as food for dogs, hogs and other animals it should first be thoroughly boiled.

The eggs of the worm reach the mouth of man directly and indirectly from the dog in various ways—through drinking water, through food soiled with dog feces, through dirty hands. Dogs lick their anal region and also lick fecal matter, and hence may directly transmit the eggs to man through licking and fondling. In an infested region, drinking water should be boiled; likewise all vegetables. Fruits and berries, especially those from near the ground, should be thoroughly washed before being eaten. Sheep and other herbivora become infected from dogs in ways entirely similar to those of man, and the principle of prophylaxis is the same.

The number of dogs should be diminished, especially stray dogs, which show a high percentage of infection. The control of the number of dogs and their habits would also help with the rabies problem. The better management of slaughter houses would not only help control echinococcus disease, but also trichinosis through rats.

## FISH

In nutritive properties, there is little difference between the muscle of fish and that of beef. In other words, fish is meat although ordinarily not so regarded. Drummond<sup>20</sup> found that the coagulable proteins of muscle tissue of the cod, herring and canned salmon have a nutritive value as high as those derived from beef; in fact, many fish contain considerable quantities of fat distributed throughout their muscle tissue, and thus probably serve as a valuable source of the "unknown dietary factor"—"fat-soluble A." The herring and also cod liver oil are rich in this vitamin. Fish resembles "meat" in that both are poor in "water-soluble B." There is, then, no essential difference in nutritive value between fish and the flesh of food mammals.

Fish poisoning or ichthyotoxismus is most frequent in Russia, Japan, and the West Indies, and other seacoast countries in which fish forms a large part of the diet. It occurs especially in warm countries.

**Physiological Fish Poisoning.**—Some fish are always poisonous, that is, normally contain a substance toxic to man; usually the poison is developed only during the spawning season. Various species of the *tetrodon* and *diodon*, which includes the puffers, balloon fish and globe fish, frequently cause serious and fatal poisoning in Japan. The most poisonous is perhaps the fugu. In Tokio alone 680 fatal cases out of 933 were reported occurring in 1885-1892 from the so-called "fugu." In China

<sup>20</sup> *Journ. Physiol.*, 52, 95, 1918.

and Japan such fish are sometimes taken for suicidal purposes. The active principle in fugu poisoning resembles curara. The poison is found mainly in the head, liver and ovaries, and called "fugin." It is not destroyed by boiling. Its chemical nature has not been determined. The symptoms produced are: dyspnea, cyanosis, dilatation of the pupils, relaxation of the sphincters, paralysis of speech, dizziness, salivation, and vomiting. Death may result in one or two hours.

Few fish containing physiological poisons are found outside of the tropics. Some fish, such as shad and smelts, are preferred during spawning season. However, during spawning season the roe of different members of the sturgeon family, of the pike, and the barbel have been said to cause pronounced and even fatal intoxication; the symptoms resemble those of gastro-enteritis. Anchovy belassa and the melite of the Indian Ocean are both said to be poisonous, the former causing death when only small amounts are taken, the latter causing violent vomiting. The Greenland shark causes an intoxication in dogs similar to that caused by alcohol. A certain degree of tolerance can be produced by feeding graded amounts. The roe of the European barbel produces the so-called "barbel cholera," while the roe of the pike is said to be poisonous during the spawning season. The toxic symptoms are said by Pozzi-Escot to occur in not less than 24 hours after ingestion. The smooth puffer (*Lagocephalus levigatus*) is considered by fishermen to be the most poisonous of the fishes of Brazil. Very little is known concerning the nature of physiological fish poisons.

**Bacterial Poisons.**—Bacterial poisoning from fish occurs. The fish may be diseased, or when caught may be healthy, but the bacteria gain access and grow throughout the meat as the result of contamination or imperfect preservation. Bacterial diseases among fish are rather common and often occur as epizootics. In almost all the reported instances of injurious action resulting from bacteria the fish has been eaten raw. Bacteria may form poisonous substances in fish closely resembling botulism. Fish caught by the gills in nets die slowly and decompose rapidly. They are of inferior flavor and value and are more liable to be injurious than fish taken from the water and killed at once; under such circumstances they remain firm and retain their flavor longer than those that die slowly. In some parts of the world live fish in tanks are offered for sale in the markets. This procedure cannot be commended from a sanitary standpoint, for the tanks are apt to become dirty and the fish liable to sicken and die slowly, so that the object of purveying only live, fresh, and wholesome fish is largely defeated. It is well known that fish decompose readily and should, therefore, be handled in a cleanly manner and used as fresh as possible. When refrigerated the temperature should be low (page 731).

"Fish poisoning" is doubtless sometimes due to a toxin produced

by *Bacillus botulinus*, or a similar anaërobe. Konstansoff<sup>21</sup> isolated an anaërobic organism from fish which had caused poisoning, and which he called *B. ichthyismi*. This organism produced a strong toxin which affects chiefly the nervous system. When administered to white mice per os, subcutaneously, intravenously or intraperitoneally, it gives rise to the same symptoms and produces the same pathologic lesions as result from ingestion of the poisonous fish. This organism is quite similar to *B. botulinus*, but Konstansoff concludes, after a careful comparison of the two organisms, that *B. ichthyismi* is a distinct entity. The symptoms caused in mice are diminution of secretions and excretions, dilation of the pupils, ophthalmoplegia, clonic and tonic muscular spasms, retention of urine and feces, and motor paralysis, which spreads gradually over the entire body, death resulting from respiratory paralysis. The heart is resistant to the action of the poison, being only slightly decreased in rate. There is, therefore, marked similarity between botulism and this form of ichthyotoxismus. Poisoning from fish contaminated with *B. enteritidis* or one of the closely allied members of the colon-typhoid group is very seldom recorded. Hypersensitiveness to fish, in the sense of anaphylaxis, is rather common.

**The Fish Tapeworm.**—The principal animal parasite conveyed through fish is the tapeworm, *Dibothriocephalus latus*, which infects man wherever fresh fish forms a large part of the diet. The larval stage or plerocercoid is found in the muscles and organs of various fresh water fish, particularly pike, perch, and several members of the salmon family, and when partaken of by man develops into the adult tapeworm in the intestines. The adult worm is also found in cats and dogs that feed upon fish.

The fish tapeworm produces a severe anemia resembling pernicious anemia. The head of the *Dibothriocephalus latus* is armed with hooks and attaches itself to the mucous membrane of the bowels. Faust and Tallqvist have shown that the anemia is due to an hemolytic action caused by oleic acid found in the head of the fish tapeworm. Each link of the fish tapeworm has a rosette-shaped uterus in the median line and a special uterine pore from which eggs are constantly discharged

FIG. 85.—*DIBOTHRIOCEPHALUS LATUS*, THE FISH TAPEWORM.  
Produces serious anemia.

<sup>21</sup> *Vestnik Obshtshestvennoy Hygieny*, 1915, 51, 1, p. 766.

and may readily be found in the feces. It is through the pollution of the streams with sewage containing the eggs that the fish become infected, but the larvae that hatch from the eggs, however, first have to pass through a procercoid stage in small crustacea (Cyclops), and the infected crustacea is then ingested by the fish.

The prevention of infestation with the fish tapeworm consists in proper disposal of feces, so as to prevent the contamination of fresh water streams, and the proper cooking of fish.

*Paragonimus westermanii*, a fluke (distome) common in Japan and other countries, produces very serious lesions in the lungs, clinically resembling tuberculosis. The parasite is contracted through fresh water crabs.<sup>22</sup>

## SHELLFISH

Shellfish include mollusks, as oysters, clams, mussels, and crustaceans, as lobsters, crabs, and shrimp. The conditions which render such food injurious are much the same as those discussed in connection with fish. Shellfish may be diseased when taken from the water, but little is known of the diseases of shellfish that influence men. Shellfish may be perfectly good and wholesome when fresh, but may become contaminated and poisonous on keeping, especially if not kept cold. Shellfish have a bad reputation, whereas it is very seldom that they are responsible for illness. Hypersusceptibility of these foods is rather common, but in this case the trouble is not with the food, but with the person who eats it.

On being transferred to fresh, clean water they may lose these injurious characteristics. Man has made shellfish a danger to himself by polluting the water in which they live. It is claimed by some observers that 6 days, by others that 16 days, in clean water are sufficient for mollusks to purge themselves of typhoid infection.

It is now well known that oysters, and doubtless other mollusks, while in polluted water, may take up large numbers of different kinds of bacteria, and that these remain alive and virulent for a long time. Herdman and Boyce found 17,000 colonies from an oyster obtained from the neighborhood of a drain pipe. Ordinarily oysters from open waters contain less than 100 colonies. Oysters contain fewer bacteria during the winter months (December to March), when they probably hibernate. Oysters placed in polluted waters may retain the typhoid bacillus as long as 14 days after they become infected. Klein found typhoid to persist in oysters from 2 to 3 weeks. At times the oysters clean themselves in a week; this is facilitated by clear, clean, running water. Recently, it has been shown that oysters may be purified in 24

<sup>22</sup>Nakagawa, *Jour. Parasitology*, 1916, II, 3, p. 111.

hours by adding bleach to the water in which they are floated. Phelps found that two days was sufficient to cleanse the oysters.<sup>23</sup> The process by which the oyster rids itself of bacteria is perhaps both mechanical and biological.

Gorham<sup>24</sup> has shown that during cold weather (40° to 45° F.) oysters rest or hibernate; the ciliary movement ceases, and feeding does not occur; and the oysters become practically free from sewage organisms even when lying in sewage-polluted beds.

Oysters reflect the bacteriology of the water in which they live and grow. The bacteria are found both in the oyster and in the oyster liquid. Oysters from clean water contain few bacteria and no *B. coli*; oysters from polluted water contain many bacteria and numerous *B. coli*. The number of *B. coli* is expressed by a "score" in accordance with the method of the American Public Health Association,<sup>25</sup> as follows:

The presence of *B. coli* in each oyster of five examined is given the following values, which represent the reciprocals of the greatest dilutions in which the test for *B. coli* is positive:

If present in 1 c.c. but not in 0.1 c.c., the value of 1.

If present in 0.1 cc., but not in 0.01 c.c., the value of 10.

If present in 0.01 c.c., but not in 0.001 c.c., the value of 100, etc.

The addition of these values for five oysters would give the total numerical value for the sample and this figure would be the score for *B. coli*.

Oysters scoring less than 50 are usually passed as satisfactory, whereas those scoring over 140 are regarded as polluted by sanitary authorities.

Both typhoid and cholera have been convincingly traced to infected oysters. The oysters may become infected where they grow or during the process of "fattening" or "floating," which consists in soaking them in fresh water for the purpose of making them more plump and increasing their size. In the language of the fishermen, this is called "floating," "plumping," "drinking," or "laying out." On account of the difference in osmotic pressure the water enters the cells of the oysters and certain mineral salts pass out. While the oyster increases in size and weight it is at the expense of the natural salt, mostly sodium chlorid, which the oyster contains. Floating is practiced by the majority of oyster growers, partly from necessity, for purchasers do not seem to realize that an oyster in its natural condition is never very thick and has a slightly greenish color.

It may be stated, as a general rule, that oysters and other shell-

<sup>25</sup> *Am. Jour. of Public Health*, II, 1912, 34.

fish should not be used when taken from water which, upon bacteriological examination, would render it unfit if used for drinking purposes.

**Outbreaks of Typhoid Fever Traced to Oysters.**—At Middletown, Connecticut, Professor Conn<sup>26</sup> showed that the outbreak of typhoid fever at Wesleyan University during 1894 was due to raw oysters eaten at fraternity banquets.

The increased prevalence of typhoid fever in Atlantic City, N. J., during the summer and autumn of 1902 was traced by Pennington<sup>27</sup> and others to the use of oysters and clams floated in Penrose Canal, which was highly polluted with sewage.

Dr. Bulstrode<sup>28</sup> during 1902 reported 21 cases of typhoid fever and 118 cases of gastro-enteritis from a total number of 267 guests who had eaten raw oysters at the mayoralty banquets at Winchester and Southampton, England, on November 10th of that year. The oysters in question were imported from France and "laid down" or floated for a few days in sewage-polluted "drinking" grounds at Emsworth. One patient who developed a fatal case of typhoid ate only one infected oyster, while others ate only two or three of these oysters.

During the period from 1894 to 1902, inclusive, Dr. Newsholme, of Brighton, England, investigated 241 cases of typhoid fever which he ascribed to eating infected shellfish.<sup>29</sup>

During the year 1902, Thresh and Wood<sup>30</sup> reported in the county of Essex, England, 4 cases of typhoid fever and 21 cases of illness due to eating Portuguese oysters sold on August 14 and 21 of that year.

Soper,<sup>31</sup> 1905, showed that 21 out of 31 cases of typhoid fever at Lawrence, Long Island, N. Y., could be traced to eating oysters and clams which had been floated or grown in Jamaica Bay, near Inwood, Long Island.

Netter<sup>32</sup> reported 33 cases of typhoid fever due to eating oysters from Cette in 1907. The cases were very virulent in character, 7 of the 33 resulting fatally.

Stiles<sup>33</sup> investigated an outbreak following the Minisink banquet, held at Goshen, N. Y., on October 5, 1911, and showed conclusively that the "Rockaway" oysters served on that occasion were responsible. There were 17 well-defined cases of typhoid fever, with one death, and 83 cases of gastro-enteritis (diarrhea) traced directly to eating "Rock-

away" oysters from Jamaica Bay, floated at Indian Creek, near Canarsie, Long Island, N. Y.

Fuller <sup>34</sup> reviewed the literature on this subject which covered more than 20 separate outbreaks due to infected shellfish up to 1904.

In Great Britain more than in other European countries, shellfish transmission of typhoid fever is regarded as quite frequent. In 1896, Newsholme, then health officer in Brighton, published careful studies showing that 30 per cent. of the typhoid infections occurring in that city were due to oysters and other shellfish. For Belfast, the investigations of Mair showed that the extensive increase of typhoid fever from 1897 to 1909 was due in a large measure to infection from cockles gathered along a shore not far from the main sewer outlet (page 124).

The prevention of typhoid and similar infections through oysters, clams, and other shellfish consists in regulating the location of the beds and in transferring doubtful oysters to a clean situation in clear sea water until the bacteria have perished or have been washed away. How long this may take is somewhat doubtful; perhaps a week, or, better, 16 days, should be allowed. "Floating" in water of doubtful character should be prohibited. Thorough cooking will kill all these non-spore-bearing bacteria.

**Mussel Poisoning.**—*Mytilus edulis*, the common mussel, is a source of poisoning in England and on the Continent. Mussel poisoning is a comparatively rare occurrence. Savage <sup>35</sup> has summarized the cases reported in Great Britain, finding that from 1827 to 1909 there were 61 cases, 8 of which were fatal—a case mortality of 13 per cent. Figures for the Continent and America do not seem to be available, but in all probability they do not exceed those of Great Britain.

The cause of "mussel poisoning" is not known. It is highly probable that the trouble comes from bacteria of intestinal origin, for all the mussels which have caused illness have invariably come from sewage polluted waters.

Three clinical types have been described: (1) An erythematous type, which is doubtless anaphylactic and not an instance of actual "poisoning"; (2) a gastro-enteric or intestinal type; (3) a paralytic type. The difference in the last two types of poisoning is one of degree, the symptoms apparently varying with the virulence and amount of the poison and the susceptibility of the individual.

The chief symptoms observed <sup>36</sup> have been referable to the central nervous system, suggestive of a powerful neurotoxin such as found in

<sup>34</sup> U. S. Bureau of Fisheries Rept., 1904, pp. 189-238.

<sup>35</sup> Rep. to the Loc. Govt. Bd. on Public Health and Medical Subjects, No. 77, 1913, p. 5.

<sup>36</sup> Savage, *ibid.*; Osler: "Principles and Practice of Medicine," 1918, p. 409; Thesen: *Arch. f. Exp. Path. u. Pharmak.*, Bd. XLVII, Hefte 5 u. 6; Rolfe: *Lancet*, Aug. 27, 1904.

botulism and possibly in ichthyotoxismus. The onset of symptoms usually comes shortly after ingestion of the mussels, but is sometimes delayed 18 to 24 hours. The common symptoms of food poisoning—nausea, vomiting, abdominal pain and diarrhea—are usually present, though they may not always be. Giddiness, vertigo, a tingling prickly sensation in the hands and feet, a sense of constriction and dryness of the mouth and throat, difficulty in speaking and swallowing, a feeling of numbness about the mouth, gradually spreading to the arms, and great muscular weakness are reported. There is usually no fever. The pupils are dilated; but react to light. There may be mental excitement very similar to that of the early stages of alcoholic intoxication. The heart is not involved, the pulse is full and bounding, but usually rapid. Dyspnea, difficult breathing, swelling of the face, lack of muscular coördination and muscular spasms may be present. Sudden syncope is not uncommon and usually immediately precedes death. Death may occur in 1 or 2 hours accompanied by all the symptoms of collapse.

The paralytic type suggests curare. This is less frequent and more dangerous than the gastro-enteric types. It may be compared with botulism, but differs in rapidity of onset, the nature of the symptoms, and in the fact that boiling does not destroy the poison. Death has occurred in 15 minutes after eating boiled mussels. A notable example of mussel poisoning occurred at Wilhelmshaven in 1885. A large number of dock laborers and their families were poisoned shortly after eating cooked mussels; three died. The mussels were examined by Brieger and Salkowski, who isolated several basic substances or "ptomains," one of which, mytilotoxin, was poisonous to animals, causing similar symptoms.

*Mytilotoxin* ( $C_6H_{15}NO_2$ ) is said to produce the same symptoms in animals which result from "mussel poisoning" in man. Novy considers this a true instance of a heat-resisting alkaloidal-like poison or ptomain in a sense analogous to mushroom poisoning. Cats and dogs eating poisonous mussels are said to suffer with symptoms similar to those seen in man, namely, paralysis, coma, and death. Rabbits have been poisoned by giving them the water in which the mussels have been cooked.

Thesen<sup>37</sup> isolated from mussels taken from the harbor of Christiania a toxic substance which resembles mytilotoxin in some ways. He has, however, not been able to convince himself that the two substances are identical. He believes that the poisonous quality of the mussels is not the result of bacterial action or of pathological metabolic processes within the mussel, but rather is due to the absorption of poisonous substances from the water. He bases his belief upon the fact that clean mussels when placed in clean water to which has been added curare,

<sup>37</sup> *Arch. f. Exp. Path. u. Pharmak.*, Bd. XLVII, Hefte 5 u. 6.

strychnin or an extract from poisonous mussels, acquire the poisonous quality of the water.

Savage is impressed with the incompleteness of our knowledge concerning mussel poisoning and concludes that:<sup>38</sup>

"Many explanations have been advanced to account for the causation of mussel poisoning. These are carefully reviewed by Bulstrode in his report (1894-95) to the Local Government Board on 'Oyster Culture in Relation to Disease.' The earlier views ascribing the pathogenic properties to copper poisoning, star-fish spawn, mussels eaten during the spawning season, mussels eaten in a stale or dead condition, may be dismissed as untrue or inadequate as explanations generally applicable although metallic poisoning cannot be excluded as a possible cause of illness in individual cases or even in small outbreaks.

"The rapidity of onset and (when fatal) rapidly fatal result make it evident that the symptoms are due to a chemical poison, while the peculiar symptoms differentiate this type from the ordinary food poisoning outbreaks.

"The most probable view is that mussels become poisonous from the production in them of chemical poisons elaborated by the vital activity of bacteria derived from their sewage-contaminated surroundings, but we are ignorant of the special bacteria concerned, the conditions which cause the production of these poisons, and whether the toxic properties are due to mytilotoxin or to some other bacterial poisons.

"Very few outbreaks appear to have been reported in recent years, but it is desirable that the whole subject should be reinvestigated by modern methods."

The prevention of mussel poisoning, on the basis of present information, rests primarily upon the prevention of sewage pollution of waters in which the mussels grow. Cooking does not seem to render them safe. Rolfe<sup>39</sup> reports two cases, one of which was fatal, from mussels which had been carefully washed and then thoroughly cooked in several changes of water. Poisonous mussels<sup>40</sup> are said to produce a sweetish, nauseating, bouillon odor. They are less pigmented and their shells are more easily broken than those of non-poisonous mussels. Their livers are larger and more mellow. The water in which they are boiled appears bluish, while that of healthy mussels is light in color. The meat of poisonous mussels is yellow, that of healthy mussels, whitish. Healthy mussels produce almost no change in alcohol, but the poisonous mussels cause the appearance of a deep golden yellow color. In spite of these differences between healthy and poisonous mussels, there seems to be

<sup>38</sup> "Food Poisoning and Food Infections," Cambridge, England, 1920, pp. 132-33.

<sup>39</sup> *Lancet*, Aug. 27, 1904.

<sup>40</sup> Edlemann, Mohler, and Eichhorn: "Meat Hygiene," Lea & Febiger, 1911, p. 350.

no ready means by which the consumer can tell whether or not the mussels are toxic.

Of interest in connection with mussel poisoning is the so-called *snail poisoning*, which has come to be associated with a certain marine snail (*Murex uradatus*). It is not known whether this snail, which is sometimes used for food, contains, under certain conditions, a substance which is poisonous to man, whether pathogenic bacteria are present, or whether preformed bacterial toxins are the cause of the symptoms in man.

### “BOB-VEAL”

“Bob-veal” is the flesh of immature calves, that is, animals less than two or three weeks old. “Bob-veal” is objectionable only from humanitarian and esthetic grounds, not from a health standpoint. The prejudice against “bob-veal” is illogical. The meat is flabby, edematous, soft. The connective tissue is gelatinous and is present in greater quantity than in mature animals. The fat is reddish-gray and soapy, the meat less nutritious in value, as it contains a large proportion of water. The digestibility of the protein of “bob-veal” is the same as market veal, namely, 93 per cent. On account of its moist and soft condition “bob-veal” has a greater tendency to spoil than the flesh of mature animals. Young calves are highly susceptible to a number of infections, particularly diarrheal diseases and infections which enter through the navel. Trouble, however, has seldom been traced to “bob-veal.”

Ostertag states: “Putrefactive and pathogenic microbes find ready media for luxuriant growth in ‘bob-veal’ carcasses. In Switzerland 27 persons became ill from eating veal of a calf five days old, which had yellow water in the joints; one patient died.”

Bollinger recites: “At Berminstorf 8 people died from eating veal from a calf four days old. At Morselle, Belgium, 80 people became sick from eating veal of two calves with diarrhea.”

It is a well-known fact that calves under three weeks old have umbilical wounds which are liable to become infected. All young animals are subject to such infections, since nature is left to effect the healing of the wound. The weight of the calf is often taken as an indication of its age. Thus a calf weighing 40 pounds or more is considered mature, but the weight is a poor index of age. The condition of the umbilical wound usually tells the tale. There are no sanitary objections to the use of “bob-veal”; infections may be guarded against by care, inspection and finally by thorough cooking.

## EGGS

Perhaps no article of diet of animal origin is more commonly eaten in all countries and served in a greater variety of ways than eggs. Eggs are used in nearly every household in some form or other. It has been calculated that on an average they furnish 3 per cent. of the total food, 5.9 per cent. of the total protein, and 4.3 per cent. of the total fat used per man per day. When we speak of eggs we ordinarily mean hen's eggs, but the eggs of ducks, geese, and guinea fowls are used to a greater or less extent; more rarely turkey's eggs and sometimes those of wild birds. Plover eggs are prized in England and Germany, while in this country the eggs of sea birds, such as gulls, terns, herons, and murre, have long been gathered for food. Other eggs besides those of birds are sometimes eaten. Turtle's eggs are highly prized in most countries where they are abundant. The eggs of the terrapin are usually served with the flesh in some of the ways of preparing it for the table. Fish eggs, especially those of the sturgeon, are preserved in salt under the name of caviar. Shad roe is also a familiar example of the use of fish eggs as food. The eggs of alligators, lizards, serpents, and some insects are eaten by races who lack the prejudices of western nations.

Very large quantities of eggs are now broken out, mixed, frozen, or dried. These products are largely employed by bakers and others who use eggs in quantities.

Hen's eggs vary considerably in size and appearance. The shell constitutes about 11 per cent., the yolk 32 per cent., and the white 57 per cent. of the total weight of the egg. The egg-shell consists mainly of carbonate of lime, and when freshly laid is covered by a mucous coating. The egg-white consists of 86.2 per cent. of water, 12.3 per cent. nitrogenous matter, 0.2 per cent. fat, and 0.06 per cent. ash. The yolk consists of 49.5 per cent. water, 15.7 per cent. nitrogenous matter, 33.3 per cent. fat, and 1.1 per cent. ash.<sup>41</sup> These are averages; different eggs vary somewhat in composition from each other. It is noteworthy that eggs contain practically no carbohydrates.

**Nutritive Value.**—The egg contains all the chemical complexes necessary for the formation of the chick during incubation. Eggs therefore furnish everything needed for the nutrition of a mammal. The egg is indeed a complete food, but not one which produces the optimum results when employed as the sole source of nutriment. Aside from the calcium content of the white and yolk of the egg, which is much lower than that of milk, the contents of the egg resemble milk in a general way in nutritional value. The high content of milk sugar in the latter,

<sup>41</sup> Pennington: "A Chemical and Bacteriological Study of Fresh Eggs," *Jour. Biol. Chem.*, Vol. VII, No. 2, Jan., 1910, p. 110.

and the almost complete absence of carbohydrate from the egg, cause them to differ considerably in the physiological results which they produce on animals when each is fed as the sole source of nutriment. Egg, when fed alone, encourages much more than milk the development of putrefactive organisms in the alimentary tract. The shell of the egg consists principally of calcium carbonate, and during incubation this is to some extent dissolved and absorbed for the formation of the chick. When eggs serve as human food the shells are discarded. These are distinct differences in the chemical natures of the constituents of eggs as contrasted with milk. The principal protein of egg yolk, like that of milk, contains phosphorus, but the fats of milk are phosphorus free, whereas phosphorized fats (that is, lecithins) are very abundant in egg fats. There is an abundance of lactose in milk, whereas the egg contains but a trace of sugar. These differences have little, if any significance. The yolk is especially rich in both the "fat-soluble A" and "water-soluble B." (McCollum.)

**Classification.**—In addition to fresh and refrigerated, eggs are classified in the trade as "rots," "spots," "checks," "ringers," "chickens," "dirty shells," "heated," or "incubated," etc. Eggs are assorted by inspection and candling. Candling consists in holding them before a bright light; the egg is translucent and the movable yolk may clearly be discerned, as well as the air space which is always at the larger end. A practiced eye quickly detects eggs that are not first quality. Rotten eggs are distinguished as "red rots" and "black rots," depending upon the kind of putrefaction. By "spots" are understood eggs that contain opaque spots under the light. These spots usually consist of local growths of mold that have penetrated a crack in the shell, although they may be due to coccidia, embryos, or foreign bodies. "Checked" eggs are those which have slight cracks or nicks in the shell. "Ringers" contain small embryos of about two days' growth, which are flat, disk-like, and reddish in appearance. "Chickens" contain embryos of larger growth. Eggs with dirty shells are undesirable more from esthetic than other reasons. The dirt usually consists of hen excrement. A "heated" egg is a shrunken egg, that is, an egg that has been exposed to the summer temperature for several days. Some water is lost by evaporation through the porous shell, the air sac on the end has increased considerably in volume, and in many instances the embryo is partly developed; therefore, heated eggs are also known as incubated eggs. Many of the eggs gathered during the hot months of summer, especially in July and August, belong to this category. These eggs are much less desirable than the spring and fall layings. Eggs are also graded as to size, the very small eggs being undesirable, commanding a lower figure in the market. Further, eggs are classified as strong- or weak-bodied, depending upon how they "stand up" when broken out.

**Bacteria in Eggs.**—Eggs as they come from the hen frequently contain bacteria, worms, gravel, blood clots, and foreign bodies of various kinds. Practically all eggs contain bacteria, although numerous observers report occasionally that an egg is sterile. As a rule, these observations are based upon planting a small part of the egg. If the entire egg is planted a growth is almost invariably obtained. Thus, in eighteen freshly laid eggs which I examined every one of them contained bacteria in the yolk; two of them contained *B. coli*. Curiously enough, there are practically always more bacteria in the yolk than in the white; the white contains some bactericidal property, probably similar to that possessed by fresh blood. The bacteria doubtless gain entrance to the egg while in the oviduct. Pernot<sup>42</sup> examined the eggs from over the size of a pea to the perfect egg and found bacteria at every stage. It is well known that the bacteria may also get into an egg through the shell, as it is porous and permeable. When the shell is moist and dirty the chances of growth and mold piercing it are increased. Eggs laid in the summer time (July and August) contain many more bacteria than those laid in the spring, fall, and colder months. It is well known that summer eggs do not keep as well as winter and spring eggs.

**Eggs and Disease.**—Of all foods, so far as known, eggs are less liable to convey disease or contain harmful properties than any other single food of animal origin. The literature is singularly free of instances of sickness attributed to eggs. There is no known infection of the hen transmissible to man through its egg. Eggs do not agree with some people, who have an "idiosyncrasy," so that a very small quantity will bring on symptoms resembling anaphylaxis. This condition is doubtless an instance of specific hypersusceptibility to egg protein. There are several cases on record in which this hypersusceptibility has been cured by the administration of pills or candy containing at first infinitesimal amounts of egg-white, gradually increasing the amount. The entire treatment should extend over a period of months. In this way an "immunity" may be established in man precisely analogous to the desensitization which may be established by repeated injections of an alien protein into guinea-pigs.

## PLANT FOODS

Man is still a parasite living on the plant kingdom. The vegetable world furnishes us our chief source of energy. The animals which furnish food to man function as expensive converters of the energy of plants into a form directly available for our uses. A cow eats a liberal

<sup>42</sup> "Investigation of the Mortality of Incubator Chicks," *Bull.* 103, Oregon Agr. College Exp. Station.

plant ration daily during several years before the nutrient products which she furnishes are ready for the market.

For purposes of nutrition, plant foods are classified as seeds; roots and tubers; and leafy vegetables. Each class has distinct dietetic qualities.

### *THE NUTRITIVE VALUE OF PLANTS*

**Seeds.**—Seeds are storage organs and can be classed together so far as their food value is concerned. The proteins of seeds are incomplete, because they contain only a few of the 17 or 18 amino-acids necessary to rebuild human protein. Seeds are also poor in mineral elements, especially calcium, sodium, and chlorin. McCollum examined wheat, corn, rice, oats, barley, rye, Kaffir corn, millet seed, flaxseed, pea, and both navy and soy beans. All, with the exception of millet seed, were below the optimum in their content of the dietary factor “fat-soluble A.” Seeds are also deficient in “water-soluble B” and in antiscorbutic properties. When seeds alone are used as the sole source of nutriment, it is not possible to secure appreciable growth in young animals.

**The Leaf.**—The leaf is very different from seeds, roots and tubers from a dietary standpoint. The leaf of the plant is very rich in cells, and in most cases contains but little reserve food material. It is the synthetic laboratory of the plant. It builds up proteins, starch, sugars and fats, through the action of chlorophyl and sunlight upon  $\text{CO}_2$ , which is absorbed from the air, together with water and mineral salts which are absorbed from the soil through the roots. The surfaces of the leaf are a mosaic of living cells. They contain all the chemical complexes which are necessary for the nutrition of the animal cells, and are qualitatively complete foods. The freer a leaf is from the function of a storage tissue, the more intensified will be its leaf properties as a food. The fleshy leaves tend to have in some degree the dietary properties of the seed, and stand intermediate between leaves which are thin, and dry easily, and the seed in this respect. In general, leaves are analogous to cellular organs of animals, such as liver, pancreas and kidneys, in dietary properties.

The dry leaf usually contains from three to five times as much total ash constituents as does the seed, and is always especially rich in calcium, sodium, and chlorin, in which the seed is poor. It follows, therefore, that the leaf supplements the inorganic deficiencies of the seed. The leaf, in most cases, contains much more of the dietary essential, “fat-soluble A,” than is found in any seed, so that combinations of leaf and seed prove more satisfactory for the nutrition of an animal than do mixtures of seeds alone. The leaf as well as the seed contains protein and amino-acids, which result from the digestion of proteins. The amount varies from 8 per cent. of protein ( $\text{nitrogen} \times 6.38$ ) in such

fleshy leaves as the cabbage, after drying, to more than 15 per cent. in the dry alfalfa or clover leaf. The seeds vary in their content of protein from about 10 to 25 per cent. The leaf proteins appear, from the data available, to supplement and enhance in some degree the value of the seed proteins with which they are combined. The leaf supplements, therefore, all the nutritive deficiencies of the seed, but not necessarily in a highly satisfactory manner.<sup>43</sup>

Peoples who have employed the leaf of the plant as their sole protective food are characterized by small stature, relatively short span of life, high infant mortality, and by contended adherence to the employment of the simple mechanical inventions of their forefathers. Contrast with Milk, page 753.

**Tubers.**—After the seeds, the tubers of certain plants constitute one of the most important classes of energy-yielding foods. The potato and sweet potato are by far the most important representatives in this group in Europe and America, but several other kinds of tubers are widely used as human food in the Orient.

**Roots.**—Roots are tubers; like the tubers, there is a cellular layer at the periphery, and the interior is loaded with reserve foodstuffs. Feeding tests have shown that the properties of the beet resemble those of the seed and tuber rather than those of the leaf. The fleshy roots and the potato and the sweet potato have an inorganic content which resembles that of the seed in a general way.

**Fruits.**—The chief uses of fruits in the diet depend upon their salt content, their laxative properties, and their antiscorbutic value. Fruits do not rank high as sources of energy to the body; that is, their caloric values are rather low in comparison with most of the common food products. Fruits are almost without exception devoid of fats and are poor in protein. They are good sources of mineral salts. Some of them contain carbohydrate, such as the sugars in the orange and the banana. They all have a high percentage of water. The citrus fruits are rich in organic acids. They are highly palatable and exert a favorable influence on the excretory processes of the kidneys and the intestine. Many of them are rich in "water-soluble B" and antiscorbutic vitamins. The liberal use of fruits in the diet should be encouraged.

**Carbohydrate Food Preparations.**—Carbohydrate foods, such as flour, sugar, starches, and most cereal preparations, are rich as sources of energy, but poor in vitamins.

## HOW PLANTS MAY INJURE HEALTH

**Poisonous Plants.**—Many plants contain a physiological poison, such, for example, as aconite, strychnin, ricin, abrin, muscarin, and a long list

<sup>43</sup> McCollum, E. V.: "The Newer Knowledge of Nutrition," The Macmillan Co., 1918.

of other substances normally present. According to Chestnut,<sup>44</sup> there are about 500 species of plants in North America which are said to be poisonous. Most of these are rare specimens, and never eaten by man; some are poisonous only during certain seasons of the year; others are poisonous only when introduced parenterally into the human body; still others, such as the poison ivy, are injurious only to susceptible individuals, while many of them are known to be poisonous only to domestic animals. Of these latter, the larkspur (*Delphinium*), the water hemlock (*Cicuta maculata*), the lupines, the laurels, and the death camus (*Zygadenus*) are prominent examples.

Chestnut estimates that in the United States there are only about 30 species of plants which have been associated with poisoning in man, and furthermore most of such cases must be considered as extremely rare accidents. Instances of such accidents have been recorded by Jordan,<sup>45</sup> who cites the mistaking of the American false hellebore (*Veratrum viride*) for the marsh-marigold; the use of the fruit of the Kentucky coffee tree (*Gymnocladus dioica*) in mistake for that of the honey locust; the use of daffodil bulbs for food; the substitution of the mountain laurel (*Kalmia latifolia*) for wintergreen, and the mistaking of the water hemlock (*Cicuta maculata*) for other edible roots. Jordan feels that poisoning from the latter cause is probably more frequent than supposed, saying that in one year, in New Jersey alone, ten cases, two of which were fatal, occurred. Ford<sup>46</sup> reports accidental poisoning in man following ingestion of the tutu plant, one of the *Eoriariae*, found chiefly in New Zealand. Roberto and Jelmoni<sup>47</sup> record an instance of poisoning following the ingestion of the berries of *Taxis baccata*, the European yew tree. Guerrero, de la Paz and Guerrero<sup>48</sup> report cases of poisoning from the use of a decoction of "Sanki," the fruit of *Illicium religiosum*, Siebold; they call attention to the great similarity between *Illicium religiosum* and *Illicium anisatum*, which, they say, is extensively used by the Filipinos as a stimulant, stomachic and carminative. The manuals on poisonous plants cite many other instances of accidental poisoning, due to the substitution, usually by children and the ignorant, of poisonous plants for similar food plants.

There is a great variation in the toxicity of plants, and tropical plants are more often poisonous than those of cooler climates, as is the case with fish, insects, snakes, and other animals.

*Mineral substances* in plants rarely cause poisoning. Lead, in grass, has been shown to be the cause of symptoms of lead poisoning in cows, and plants manured with superphosphates which contain arsenic may

<sup>44</sup> *Science*, XV, 1902, 1916.

<sup>45</sup> "Food Poisoning," Univ. of Chicago Press, 1917, p. 4.

<sup>48</sup> *Philippine Jour. Sci.*, Sept., 1916, XI, p. 203.

absorb enough arsenic to cause sickness.<sup>49</sup> Similarly, there is possibility of poisoning due to the use of insecticidal sprays, washes and powders, on vegetables and fruits. See page 279.

*Acids* are of more common occurrence. Prussic acid occurs free in some plants, as a glucosid in some others, especially in those of the rose and apple family. The bitter cassava (*Manihot utilissima*), from which ordinary tapioca is derived, contains prussic acid in considerable amount, and cannot be eaten in the fresh state. The prussic acid is dissipated by heat. Cases of poisoning due to this cause are not known.

Oxalic acid is quite common in many plants, and illustrative of its poisonous qualities is the outbreak of so-called "ptomain poisoning" reported in New York,<sup>50</sup> which was shown to be due to soup prepared from "Schav" or "Szhav" leaves, more commonly known as sour grass—a species of sorrel. Two grains of oxalic acid were found in each ounce of the leaves, and four grains in each ounce of the stems of this plant. The soup which was eaten contained about ten grains of oxalic acid per pint. Robb<sup>51</sup> reports a fatal case of oxalic acid poisoning due to eating fried rhubarb leaves. Marked exhaustion, hemoptysis, early cardiac failure, and greatly delayed coagulation time of the blood were the prominent symptoms observed in this case. The oxalic acid content (as oxalates) of the stalks of rhubarb varies from 1.5 per cent. to 40 per cent.,<sup>52</sup> but there seems to be no figure available for the amount in the leaves. Arbenz<sup>53</sup> found that rhubarb contains 3.2 grams of oxalic acid per kilogram. Many other foods contain oxalic acid, but in harmless amounts. The poisonous qualities of the loco weed (*Astragalus mollissimus*), common to the western states, have been attributed to an acid present in the plant, called by some "loco" acid.

*Oils*.—Some of the common vegetable *oils*, such as the oils of chamomile, cloves, cinnamon, sassafras, etc., may be poisonous in excessive amounts. Chestnut<sup>54</sup> cites an instance of the death of a child following the ingestion of two nutmegs, while Jordan<sup>55</sup> calls attention to an outbreak of sickness in Germany in 1911 due to the inclusion of maratti-oil (from the tropical plant *Hydrocarpus*) in a commercial substitute.

**Carotinemia.**<sup>56</sup>—A diet rich in carotin, which is the coloring matter contained in carrots, spinach, egg yolk, and oranges, may produce a yellow discoloration of the skin, which resembles jaundice, except

that the sclera are not involved. The carotin and xanthophyll pigments derived from food are the sources of the coloring matters of milk fats and body fats, of egg yolk, of the corpus luteum, nerve cells, and other structures.<sup>57</sup>

**Parasites.**—Certain vegetables, such as lettuce, celery, water cress, radishes, and similar plants, eaten raw may convey typhoid fever, cholera, dysentery, both amebic and bacillary, the eggs and larvae of animal parasites, and other agents of infection. This usually occurs from the use of night-soil as fertilizer, or from infected water from a foul source.

All vegetables which are eaten raw should be washed thoroughly beforehand, otherwise they may be contaminated with manure and other impurities or the excrement of domestic animals which have been roaming in the garden. The larvae of worms have been transmitted to man in this manner.

A fungus developing in rye is responsible for ergotism. Molds and smuts which grow on plants used by man for food may give rise to serious difficulty due largely to mechanical obstruction, although there is some reason to believe that poisonous substances may be formed, for example, the sulphocyanic acid formed by *Aspergillus niger*.<sup>58</sup> Ernst<sup>59</sup> reports a case of mucor infection, suggestive of pulmonary tuberculosis, in which the source of the mucor was probably corn.

**Toxins.**—Bacteria growing in plants may develop toxins. Botulism is the only known example in this category. This poison may form in beans, corn, peas, asparagus, beets, olives, and a variety of other plant foods containing protein.

**Susceptibility, Idiosyncrasy, Anaphylaxis.**—A number of plant foods, such as strawberries, tomatoes, oatmeal, etc., cause urticarial eruptions and other manifestations of anaphylaxis in susceptible individuals. Hay fever is another instance of hypersusceptibility, brought on by the pollen of various plants. These conditions are discussed under the chapter on Anaphylaxis, page 593.

**Rhus Poisoning.**—Rhus poisoning, also known as *Rhus dermatitis*, or *Dermatitis venenata*, is caused by an irritating resinous substance in the sap of numerous plants. The various plants which may provoke such irritation in susceptible subjects are at least 60 or 70 in number. The most common and best known of this group belong to the genus *Rhus*. *Rhus toxicodendron*, or poison ivy, is distinguished from other suspected creepers of a similar appearance by its possession of three leaflets instead of five. *Rhus diversiloba*, or poison oak, which grows especially

<sup>57</sup> Palmer, L. S., and Eckles, C. H., *Jour. Biol. Chem.*, XVII, 191, 211, 223, 237, 245, March, 1914; also Palmer, L. S.: *Ibid.*, XXIII, 261, Nov., 1915; XXVII, 27, Oct., 1916.

<sup>58</sup> *Science*, XV, 1902, p. 1016.

<sup>59</sup> *Journ. Med. Research*, Nov., 1918, XXXIX, No. 2, p. 143.

in the western part of the United States, is a shrub or small tree. *Rhus venenata*, known as poison sumac, poison dogwood, and poison elder, is a shrub or small tree, growing in swampy places in the United States and Canada as well as in Japan.

Of the six varieties of the rhus family that grow wild in Japan, *Rhus toxicodendron* and *Rhus vermicifera* are the most injurious. Among the plants which less frequently cause dermatitis are the nettle (*Urtica dioica*), the primrose (*Primula obconica*), cowhage (*Macuna pruriens*), smartweed (*Polygonum punctatum*), balm of Gilead (*Podophyllum. Balsamum gileadense*), oleander (*Nerium Oleander*), and rue (*Ruta*).

The part of these plants to be feared is the resinous sap. This sticky sap, exuding from all parts of an injured plant, when it comes in contact with the skin, causes intense irritation, which is characterized by its acute character, frequently beginning between the fingers, associated with swelling, and often large vesicles and blebs, the exudate from which is non-toxic. The dermatitis occurs in sharply defined patches, elongated streaks, and other irregular shapes, corresponding with the original area of contact. It does not follow the nerve trunks. It seldom attacks the scalp or the inside of the hands. The original areas of contact are most affected and the parts of the skin to which the poison has been conveyed from the original sites of contact are usually less severely affected. Together with the local lesions, there is a leukocytosis and constitutional disturbances, such as fever, coated tongue, loss of appetite, constipation, and a trace of albumin in the urine.<sup>60</sup> The attack may subside in from four to six days, depending on the amount of the irritant and the sensitiveness of the skin. Idiosyncrasy plays an important part. Persons affected are believed to be more susceptible.

It is now quite certain that the toxic principle in *Rhus* poisoning is not volatile, as was once supposed; in other words, contact is necessary, although not actual contact with the plant itself, for the sap may be carried indirectly by clothing, tools, insects, smoke, etc., to the skin of persons far from the actual neighborhood of the plant, thus explaining those mysterious "recurrent" cases of *rhus* poisoning. Sap thus carried loses its toxic properties by oxidation, the loss being more rapid at body temperature and moist atmosphere.

Japanese lacquered ware when new has caused a dermatitis in a large number of people. The sap of the lacquer tree produces typical *rhus* poisoning. Susceptible individuals may be affected by passing under a lacquer tree, or by simply going by a lacquer-ware shop. This does not mean that the poison is volatile, for in such instances the sap is transferred in some mechanical way.

<sup>60</sup> McNair, J. B.: "The Transmission of *Rhus* Poison from Plant to Person," *Jour. Infect. Dis.*, 1916, XIX, 429; "The Pathology of Dermatitis Venenata from *Rhus Diversiloba*," *ibid.*, 1916, XIX.

McNair<sup>61</sup> has shown that smoke from the heated leaves of poison oak causes dermatitis if blown on the wrist. If, however, the smoke is filtered through glass wool, it is no longer irritating, showing that the smoke is only a mechanical carrier of the poison, thus confirming the oft-repeated observation that poisoning may result from exposure to smoke of camp fires, etc. The exact nature of the chemical substance is not known, but it is now clear that it is non-volatile and resinous in nature, and that it is absent from the pollen and plant hairs. The toxic substances in the several plants are identical or very closely related. Pfaff<sup>62</sup> isolated a fixed oil, *toxicodendrol*, of which 1/1,000 milligram in two drops of oil will set up localized edema and vesication.

The dermatitis may sometimes be averted, even after handling these plants, by the free use of an alkaline soap and water, or alcohol, containing a little dissolved sodium hydroxid. The poison is soluble in alcohol and alkalies. Gasoline may also be used. An aqueous solution of sodium bicarbonate is less effective. The application must be prompt and thorough or else it will only tend to spread the irritating poison.

### POISONING FROM PLANT FOODS

**Ergotism.**—Ergotism is a form of food poisoning brought on by prolonged use of meal made from grain contaminated with the *Claviceps purpurea*. The fungus develops in the flowers of rye and other grains. The chief source of the poisoning in man is from rye, in which case the fungus may entirely replace the grain. Ergotism is practically unknown in this country, but in Europe it is still occasionally met with, although not to the same extent as in former times. From ergot Kobert was able to isolate three poisonous substances, sphacelinic acid, cornutin, and ergotin. Sphacelinic acid is a non-nitrogenous, unstable body and is believed to be the active agent in contracting the blood vessels. Cornutin is also an active alkaloid and produces vasomotor contraction. According to Novy, more recent investigations have made it probable that there are other substances present which constitute the real toxic agent. Thus, Jacoby obtained a non-nitrogenous resin sphacelotoxin and Barger, parahydroxyphenylethylamin, which they regard as the specific poisons. It is now believed that histamin is the most important constituent of ergot, for in minute doses it produces tonic contraction of the uterus.<sup>63</sup>

The intoxication may have an acute or chronic course, and in either

<sup>61</sup> McNair, J. B.: *Jour. Am. Chem. Soc.*, 1916, XXXVIII, 1417.

<sup>62</sup> *Jour. Exp. Med.*, 1897, II, p. 181.

<sup>63</sup> Barger and Dale: *Jour. of Physiol.*, XL, 38, 1910; Kutscher: *Centralbl. f. Physiol.*, XXIV, 163, 1910; Ackermann and Kutscher: *Ztschr. f. Biol.*, LIV, 387, 1910.

type the symptoms may be nervous or convulsive, or else they may be trophic or gangrenous in character.

The presence of the sclerotium may be suspected from the color of the meal, which is grayer than usual and often shows violet-colored specks. The addition of potassium hydroxid with heat produces an odor of trimethylamin resulting from the breaking up of the grain containing chinolin. Further, the grain contains a dye which is soluble in alcohol or ether. To 10 grams of the meal add 10 c.c. of ether and 20 drops of dilute sulphuric acid. Shake well and filter after half an hour. Then add several drops of a saturated solution of sodium bicarbonate, which dissolves out all the coloring matter.

**Lathyrism.**—Lathyrism or vetch poisoning is a rather rare condition met with in some parts of Europe, notably Austria and Italy, in northern Africa, and in India. The vetch seed is ground in the form of meal and used as a partial substitute for that of wheat. The seed is popularly known as chick-pea. The vetch seeds are obtained chiefly from *Lathyrus sativus* and *Lathyrus cicera*. The eating of bread prepared from meal containing the seeds of the lathyrus is followed by sudden and severe pains in the lumbar region, girdle sensation, motor paralysis of the lower extremities, tremor, and fever. The nature of the poison is not known, but it is probably of the nature of a toxalbumose, of which ricin and abrin, the poisons of the castor bean and the jequirity bean respectively, are well-known examples.

**Favism.**—Favism (*fava*, bean) is the name applied to a disease which has been reported only in Italy. It is attributed to the use of beans as food, or even just smelling the blossoms of the bean plants. Pammel<sup>64</sup> cites instances of individuals who cannot inhale the odor of morphin, turpentine, tobacco, the flowers of the common bird cherry, the haw or the tuberose, without becoming ill. Gasbarrini<sup>65</sup> quotes the work of Germeti and concludes with him that the disease is the result of an acute, toxic hemolysis. It is said to occur only where beans are cultivated on a large scale, and then usually only during the spring of the year. Of 1211 cases which were studied by Fermi in Sardinia, 752 were ascribed to ingestion of the beans, and 459 to inhalation of the odor or pollen of the bean plants. The onset of symptoms occurs a day or so after ingestion or from 2 to 6 hours following inhalation. It is distinguished by acute, febrile anemia with jaundice and hemoglobinuria, but there may also be abdominal pain, nausea, vomiting and diarrhea. Fermi noted an hereditary tendency in about 20 per cent. of his cases, which in some instances could be traced through several generations. This hereditary predisposition to the disease is said not to become apparent in some cases until adult life. It is also stated that in some

<sup>64</sup> *Manual of Poisonous Plants*, Part I, 1910, p. 7.

<sup>65</sup> *Polislinico*, Nov. 14, 1915; abstr. *J. A. M. A.*, 1915, p. 2234.

instances one exposure seems to confer a permanent immunity but others suffer at each exposure. The cause of the disease is unknown. Bacterial activity and fungi have been held responsible but no proof of either hypothesis has been brought forward. The reported seasonal prevalence, the incidence following inhalation of the bean pollen, the hereditary predisposition, and the possible immunity following one attack are suggestive of sensitization and anaphylactic reaction.

**Mushroom Poisoning.**—The ill effects from eating mushrooms are usually due to mistaking the poisonous for the edible species, and in America this is usually done by children, immigrants or the ignorant.

The number of species of poisonous mushrooms which are capable of causing death is not very great, perhaps 20 or 30. *Amanita* and *volvaria* are the most poisonous genera, and are the ones usually involved in the fatal accidents.

Ford<sup>66</sup> estimates that from 12 to 15 deaths occur annually in the United States from *Amanita* poisoning. In September, 1911, in the vicinity of New York, following heavy rains, 22 deaths were reported. Jordan<sup>67</sup> believes that mushroom poisoning is probably increasing in this country due to an increasing use of mushrooms for food, and also due to increased immigration from countries where mushrooms are more commonly eaten than here.

*Amanita phalloides* and *Amanita muscaria* are exceedingly poisonous, dangerous and seductive species, responsible for most of the deaths from toadstool eating. *Amanita phalloides*, because of its white color, is mistaken for the common mushroom. *Agaricus campestris*. *Agaricus campestris* does not grow in the woods, neither has it white gills, nor white spores, nor a volva at the base of the stem. No dependence, however, should be placed upon color, size, shape or general appearance. It requires a trained mycologist to distinguish one species from another.<sup>68</sup>

The first historic instance of mushroom poisoning occurred in the family of the Greek poet, Euripides, who lost, in one day, wife, daughter and two sons. Among others whose lives have been sacrificed through ignorance may be mentioned Pope Clement VII, the Emperor Jovia, Emperor Charles VI, Berronill of Naples, the widow of Tsar Alexis, and the Princess of Conti. Poisonous fungi have figured prominently in many of the accidental and craftily malicious tragedies of history.

Poisonous mushrooms contain at least four classes of poison: (1) a "toxin" represented by amanitotoxin;<sup>69</sup> (2) muscarin, an alkaloidal-like substance, resembling pilocarpin; (3) a hemolytic poison; and (4) a number of poisons more or less ill defined, such as the Pilcz-toxin of

<sup>66</sup> *Journ. Inf. Dis.*, III, 2, Apr., 1906, p. 191.

<sup>67</sup> "Food Poisoning," Chicago Univ. Press, 1917, p. 18.

<sup>68</sup> The subject has been discussed since 1886 in the *Bulletin de la Société Mycologique de France*.

<sup>69</sup> Wm. H. Ford: *Jour. Exp. Med.*, May 26, 1906, VIII, 3, p. 437.

Harmsen. These poisons do not all occur in any one species, but are found singly and in various combinations in the different genera and species.

*Amanita phalloides*, the "white or deadly amanita," is the cause of the greatest number of cases of mushroom poisoning, if we include in this group *A. verna*, *A. bulbosa*, *A. alba*, *A. virescens*, *A. mappa*, and many other species known by various names in different localities. Fatal poisoning takes place when the fungi are eaten raw or cooked. Two or three deadly amanitas are sufficient to cause profound illness with fatal outcome in an adult. Plowright reports the death of a child of twelve from eating a third of the pileus of a small raw plant.

In 1891 Kobert isolated from *Amanita phalloides* a substance having a powerful hemolytic action which he called *phallin*. For some time it was believed that phallin was the essential poison of *Amanita phalloides*, but Ford<sup>70</sup> showed that there is another substance present which is much more toxic, and to which most of the symptoms can probably be traced. This is supported by the fact that boiling *Amanita phalloides* mushrooms destroys its hemolytic power, but fails to neutralize its toxic action. This substance Ford has called "Amanitotoxin" and states that it has no hemolytic action, but rather produces hemorrhage and causes necrosis and fatty degeneration of the parenchymatous organs. He also succeeded in producing an antihemolysin which completely neutralizes the blood-laking properties of phallin. Clark, Marshall and Rountree<sup>71</sup> found that in cases of *Amanita phalloides* poisoning, the pathological lesions consist chiefly of central necrosis of the liver, epithelial necrosis of the kidney, acute enteritis and colitis, the kidneys being the seat of the most marked changes. They conclude that nervous and mental changes observed are probably uremic in character, and not due to some peculiar "neurotoxin."

The symptoms of poisoning by *Amanita phalloides* usually do not develop for from 6 to 15 hours after ingestion, the onset being marked by very sudden, severe abdominal pain, intense thirst, nausea, retching, vomiting and very profuse water evacuations, sometimes containing blood and mucus. A state of collapse may soon develop. There is usually a rapid loss of strength and flesh, and the patient develops a peculiar yellow color. The pupils are usually contracted; the breath is quite fetid and the mucous membranes dry and glazed, and there may be bleeding from the gums. Visual disturbances leading to confusion, delirium and convulsions may develop, but convulsions are usually due to a mixed intoxication, which in turn is due to *Amanita muscaria* being mixed with *Amanita phalloides*. After 3 or 4 days in children, and usually 6 or 8 in adults, the patients sink into a profound

<sup>70</sup> *Journ. Inf. Dis.*, III, 2, Apr., 1906, p. 191.

<sup>71</sup> *J. A. M. A.*, LXIV, 1915, p. 1230.

coma from which they do not often awake. Ford<sup>72</sup> states that the case fatality rate of *Amanita phalloides* poisoning is from 60 to 100 per cent. The danger is much less in the case of *Amanita muscaria*.

*Muscarin* is the active poisonous principle of *Amanita muscaria* (*Agaricus muscarius*, "fly" amanita). Muscarin  $(\text{CH}_3)_3\text{NOH}.\text{CH}_2\text{OH}$  is a syrupy, alkaloidal-like substance obtainable in crystallizable form as a hydrochlorid. It was first isolated by Schmiedeberg and Koppe in 1869. Chemically it evidently is an ammonia substitution compound and is classed with the ammonia bases. It may be prepared synthetically by the oxidation of cholin.

The physiological action of muscarin resembles pilocarpin very closely. It stimulates the myoneural junctions between the nerves and epithelial cells. Atropin is an almost perfect physiological antidote for muscarin, paralyzing the myoneural junctions, and is used with more or less success in mushroom poisoning.

The symptoms of muscarin poisoning come on quickly, often within 15 minutes after eating the mushroom (*Amanita muscaria*). They consist of salivation, excessive perspiration, a flow of tears, nausea, retching and vomiting, pain in the abdomen, and violent movement of the intestines, causing profuse watery evacuations. The pulse is sometimes quickened, sometimes very slow and irregular. The pupil is contracted, respiration often quickened, and dyspneic. Dizziness and confusion of ideas are often complained of, but mental symptoms are not so conspicuous as those from the peripheral organs. Mental symptoms, such as hallucinations, delirium and convulsions are attributed to the Pilez-toxin of Harmsen. Eventually the respiration becomes slower, great muscular weakness supervenes, but consciousness remains more or less clear until the breathing ceases.

The peasants of the Caucasus prepare an intoxicating beverage from *A. muscaria* which produces wildly riotous drunkenness. Death from muscarin orgies is not uncommon in this part of Russia. Similar species in Northeastern Asia are also used as an intoxicant. The poison is excreted in the urine which is sometimes later consumed for its intoxicating effect. It is probable that a sort of tolerance to muscarin is developed among the habitual users of the muscaria decoction.

The alkaloid is soluble in water and poisoning may be prevented by soaking the mushrooms in water slightly acidulated with vinegar before they are cooked.

*Hemolysin*.—Kobert in 1891 obtained a hemolytic substance by alcoholic precipitation from *A. phalloides*. This substance he named *phal-lin*; it is an extremely complicated substance, having the nature of a glucose; that is, it contains sugar in its molecule. It is not always present in *A. phalloides* and is probably not an essential poison in this

<sup>72</sup> *Journ. Inf. Dis.*, III, 2, Apr., 1906, p. 191.

mushroom, for its activity is destroyed at 70° C. and also by the action of the gastric juice. A high grade immunity can be established in animals to the hemolytic substance. Ford obtained an anti-hemolysin which completely neutralizes the blood-laking properties of this poison.

The hemolysin probably plays a small rôle, if any, in human intoxication. *A. rubescens*, considered by the majority of mycologists to be an edible mushroom, contains a powerful hemolysin. On the other hand, a hemolytic poison is found in *Helvella* or *Gyromytra esculenta* which occurs rarely in this country. The active principle is helvellic acid (Boehm and Külz) which produces in dogs all the signs of hemolytic intoxication similar to those sometimes found in man.

Morner gives eight pages of references to mushroom poisoning.<sup>73</sup>

**Potato Poisoning.**—Outbreaks of poisoning attributed to potatoes have occurred largely among troops. Schmiedeberg<sup>74</sup> reports outbreaks involving 357, 90, 125 and 101 men, respectively, and Pfuhl<sup>75</sup> records an outbreak involving 56 soldiers. In all cases, the outbreaks were attributed to potatoes, sometimes new, sometimes old sprouting ones, and sometimes potato salad.

The onset of symptoms occurs usually only a few hours after eating the potatoes. Symptoms reported have been headache, abdominal pains,\* nausea, vomiting, diarrhea, prostration, dizziness, drowsiness, and slight delirium. Fever has usually been absent. In some cases, dilatation of the pupils is reported. The symptoms only very rarely become threatening and practically all the victims recover rapidly.

These cases were long regarded as solanin poisoning,\* but it is now plain that this does not account for most outbreaks, some of which at least are bacterial in origin.

*Solanin* ( $C_{42}H_{75}O_{15}N_4$ ) is a glucosidal alkaloid closely resembling the saponins in reaction, and found in many species of *Solanum*, such as *S. nigrum* (black nightshade), *S. dulcamara* (bitter sweet), and *S. tuberosum* (potato). The solanin content is highest in the potato peel, decreasing towards the center of the potato. It has also been held to occur chiefly in immature, sprouting or diseased potato parts which ordinarily are discarded before cooking.

Toxicologic tests on man have demonstrated that 0.2 gram of isolated solanin may provoke untoward symptoms. Seldom would that amount occur in the quantity of potatoes which an adult might consume in the course of a day. Owing to variations in purity, it is not possible to state how much solanin would be necessary to cause poisoning.

<sup>73</sup> *Upsala Lakarefornings Forkandlengar*, Jan. 20, 1914, XXIV, Nos. 1 and 2.

<sup>74</sup> *Arch. f. Exp. Path. u. Pharm.*, Vol. XXXVI, 1895.

<sup>75</sup> *Deutsch. med. Wochenschr.*, 1899.

Meyer<sup>76</sup> showed that the solanin content of potatoes varied with the season, ranging from 0.04 gram per kilo during the winter to 0.116 gram during the summer. In vigorously sprouting and diseased potatoes, he found as much as 1.34 grams of solanin per kilo. Wintgen<sup>77</sup> also found a fluctuating solanin content in sound potatoes (0.017 to 0.08 gram per kilo), but the quantity was always small. Even in sprouted potatoes, he observed no increase in the solanin content, provided the sprouts were carefully removed. He was unable to find an increased amount in diseased potatoes. Wintgen was also unable to confirm the statement of Weil<sup>78</sup> that the solanin in potatoes was increased by the activity of two organisms (*bacterium solaniferum non-colorabile* and *bacterium solaniferum colorabile*). Harris and Cockburn,<sup>79</sup> in an outbreak in Glasgow involving 61 people, showed that the incriminated potatoes contained 0.41 gram per kilo of solanin, an amount which they interpret as being five or six times the normal content.

Rothe<sup>80</sup> studied a recent outbreak in Leipzig. The symptoms were abdominal pain, vomiting and diarrhea. An analysis of the same lot of tubers disclosed 0.43 gram of solanin per kilogram, which is about ten times the quantity found ordinarily in potatoes. The conclusion is drawn that the possibility of solanin poisoning must be reckoned with, especially when potatoes prematurely harvested are used as food.

It now appears probable that most instances of potato poisoning are not due to solanin, but are bacterial infections. Thus, Diendonno<sup>81</sup> reports an outbreak of poisoning attributed to potato salad, in which the solanin content was only 0.021 gram per kilo. The symptoms were identical with those usually attributed to potato poisoning. *Bacillus proteus* was present in considerable numbers in the potato salad, and when grown on sterile potato medium, a highly poisonous culture was obtained which was fatal to mice in twenty-four hours. In most of the reported cases, the potatoes were prepared at least several hours before they were eaten, and had been left in places favorable to bacterial infection. Potatoes make an excellent nutrient culture medium. Typhoid, paratyphoid, *B. enteritidis* and many other pathogenic microorganisms grow well on potato.

## SECTION VI

### AIR

#### CHAPTER I

#### COMPOSITION OF THE AIR

The air constitutes a gaseous ocean in which we live; it consists of a vast volume of gases at least one hundred miles high.<sup>1</sup> Ordinarily we speak of this gaseous envelope of the earth as the *atmosphere*, and the water resting upon the surface of the earth as the *aquasphere*, while the solid structure of the earth is called the *petrosphere*. Between the atmosphere on the one hand and the petrosphere and aquasphere on the other hand is the region of most abundant life, and this is spoken of as the *virosphere*.

The importance of fresh air was almost completely ignored in practical life until recently—thanks to the tuberculosis propaganda. While recent studies have shown that the air is not to be feared as a frequent medium for conveying specific infections, it has been demonstrated that an abundant supply of fresh air is necessary to perfect well-being. Statistical studies seem to prove that, of the predisposing causes to sickness which are usually in action, impurities of the air are perhaps the most important. This has been stated over and over again in the case of horses, cattle, and dogs, as well as of men confined in badly ventilated barracks, jails, and other places.

Many other factors are now known to be a greater menace to health than the “bad” air of crowded places; sanitarians, however, have come to regard an abundant supply of pure fresh air, well conditioned, as one of the real essentials for health and maximum efficiency. Many of the ill effects attributed to bad air are really due to crowding. Crowding forces the occupants into close personal contact and thus favors the spread of infections. It is a well recognized principle in military hygiene that in a crowded barracks, with good or bad air, there will be an excessive amount of pneumonia, sore throats, colds and other inflammatory affections of the upper respiratory passages—which at times become epidemic.

<sup>1</sup>Forty-five or fifty miles is its practical limit, and anything beyond that distance is in an extremely tenuous state.

While fresh air is so necessary to perfect well-being, nevertheless some people get along with surprisingly little, and that often vitiated. Many people sleep huddled up, with their faces completely covered as though they would suffocate. In Holland many people sleep in an arrangement not unlike a closet, and yet retain rugged health. Dogs, sheep, and animals sleep huddled up, with their faces completely covered, sometimes in caves or dens where the air must be very bad. It is evident that the factor of safety must be very large, also that the question of habit plays a conspicuous rôle, for persons accustomed to good fresh air are rendered truly miserable when confined to a close, stuffy room.

The two chief functions of the air that are especially concerned with health are (1) interchange of gases in respiration, and (2) regulation of bodily temperature. Further, it should be remembered that the combustion of the food we eat depends upon the oxygen of the air we breathe, and that digestion and metabolism are stimulated and improved by an abundant supply of fresh air or rendered sluggish and retarded by prolonged exposure to vitiated air.

The atmosphere is now known to contain the following gases in the following approximate proportions measured at 0° C. and at 760 mm. pressure:

	Volumes Per Cent.	Weight Per Cent.
Oxygen .....	20.93	23.2
Nitrogen .....	78.10	76.8
Carbon dioxide.....	0.03	
Argon .....	0.94

"Pure" air, in addition, contains water vapor in varying amounts, dust, radioactive substances, etc.

The air is a mixture of gases and not a chemical compound. The proofs of this are manifold: (1) the gases do not exist in the air in the proportion of their combining weights or any multiple of them; (2) on mixing the gases in atmospheric proportions there is no heat evolved; (3) the composition of air within limits is variable; (4) when water dissolves air it dissolves each gas according to its partial pressure and its own proper coefficient of solubility. Thus, air contains more nitrogen than oxygen, but, oxygen being more soluble, water takes up 1.87 parts of oxygen to 1 part of nitrogen.

Jean Mayow in 1669 first proved that air was not an element, but a mixture of gases, and later Lavoisier discovered the two gases which about 100 years afterwards were separated by Priestley and Sheele.

The composition of the air shows wonderful uniformity all over the earth's surface wherever examined. This is due to the enormous amount

of atmosphere and the mixing influences of air currents. However, in confined spaces where the air is not in motion, especially where decomposition of organic matter is taking place or where active combustion is going on, or in the presence of animal life, the composition of the air varies considerably.

The difference in composition between inspired and expired air, expressed as volumes per cent. at 0° C. and 760 mm., is as follows:

	O	N	CO <sub>2</sub>
Inspired air.....	20.93	79.04	.03
Expired air.....	16.	79.	5.0

The expired air is also warmer, is increased in volume, and contains more moisture, but fewer particles, such as dust and bacteria. Under normal conditions of quiet respiration the expired breath contains no bacteria.

## OXYGEN

About one-fifth (20.94 per cent. by volume, 23.2 per cent. by weight) of the atmosphere consists of oxygen, which in many respects is its most important element. Slight differences are noted; thus, the air of towns contains somewhat less (20.87 per cent. by volume) than in mid-ocean. The slight differences that have been noted in the percentage of oxygen are of no special importance. It may drop to 15 per cent. or may rise to 50 per cent. or even higher without any very apparent alteration in the vital functions. An atmosphere containing only 11 to 12 per cent. of oxygen becomes dangerous, and 7.2 per cent. results in death. In submarines, 16 per cent. is the signal to replenish oxygen from the tank. A candle goes out at 16 per cent., and an acetylene flame at 12½ per cent.

Haldene<sup>2</sup> and his collaborators have shown that oxygen deficiency (anoxemia) increases the rate of respiration, whereas accumulating carbon dioxid increases the depth of respiration without essentially altering the rate. On the other hand, long exposures to an atmosphere containing a great excess of oxygen may act as an irritant. Karsner and Ash<sup>3</sup> found that rabbits show little effect when exposed for eleven days to an atmosphere containing oxygen between 60 and 70 per cent., but above this point irritation of the lungs and pneumonia supervene.

The amount of oxygen absorbed depends rather upon the needs of the body than upon the amount in the air. About 5 per cent. of the oxygen in the air is removed by respiration.

Alveolar air normally contains about 16 per cent. of oxygen, and

<sup>2</sup> *Journ. Physiol.*, 32, 225, 1905; also 52, 420, 1919.

<sup>3</sup> *Journ. Lab. and Clin. Med.*, 11, No. 4, Jan., 1917.

the red blood cells, as they leave the lungs, are practically saturated with it. The amount taken up on their next trip through the lungs depends on how much they have given up to the tissues in the meantime, not upon how much is available for their use. The normal 16 per cent. of oxygen in the alveolar air is automatically maintained by the action of the  $\text{CO}_2$  on the respiratory center, but on account of the chemical affinity of the hemoglobin for oxygen the blood cells may still take practically their full capacity of oxygen when it is reduced to 12 per cent. or less in the alveolar air. In other words, a large excess of oxygen is constantly maintained in the air of the lungs. While it is one of the chief functions of respiration to supply oxygen to the body, neither a surplus nor a deficiency of it in the air, unless the alteration is extreme, has any effect on the respiratory movements. Breathing will not be lessened nor more oxygen taken up because more of it is supplied to the lungs; nor will the oxidation processes in the body be affected in any way, unless other influences are simultaneously brought into play. Indeed, Hender-son reminds us that it is necessary to go only a short distance up into the mountains to come under an atmospheric pressure such as to reduce the oxygen supply considerably. Yet mountain air is especially healthful. Except in extreme conditions the amount of oxygen in the closest halls crowded with people practically never falls below 20 per cent. The amount of oxygen in the air apparently has little or nothing to do with the stimulating or depressing properties of the atmosphere breathed in ordinary life.

The constant percentage of oxygen is due in part to the enormous amount of it. Flüggé estimates that at the present rate at which the oxygen is used by respiration and combustion it would take eighteen thousand years to reduce it by one per cent., even if not replaced by vegetation. The lungs, of course, at no time after the first breath contain air with the full percentage of oxygen. This is owing to the fact that the lungs do not completely empty themselves, and the residual air remaining in the lungs accumulates carbon dioxid and loses oxygen.

Oxygen is the element in the air that sustains all life. It is absorbed by the lungs, passes into the blood, combines loosely with the hemoglobin of the red blood corpuscles, and is thus carried to all the tissues and cells of the body. Oxygen in combination with the hemoglobin forms an unstable compound—oxyhemoglobin—which gives the bright red color to arterial blood. The oxygen bound with the hemoglobin in arterial blood consists of from 22 to 25 per cent. of the volume of the blood. The amount of oxygen absorbed varies with the age, condition of health, and activity. According to Professor Foster, the average person inhales in 24 hours about 34 pounds of air, which corresponds to a little over 7 pounds of oxygen. As the lungs absorb about

one-fourth of the oxygen inhaled, it appears that the average amount of oxygen absorbed daily is nearly two pounds. Oxygen also exists in its gaseous form in blood, saliva, bile, urine, and other fluids of the body, but only in minute amounts.

The amount of oxygen in the air may readily be measured in the Petterson-Palmquist or Haldane apparatus. The oxygen is absorbed by 10 per cent. pyrogallie acid in a saturated solution of KOH (sp. gr. 1.058); the difference in volume before and after absorption represents the amount of oxygen (pages 878-880).

Determinations of the amount of oxygen of the atmosphere have no particular hygienic significance.

## NITROGEN

The nitrogen in the air may be regarded as a diluent, and as inert so far as its direct action upon man is concerned. There is no appreciable difference in the amount of nitrogen contained in inspired and expired air. Nitrogen does not "dilute" the oxygen, and thus regulate respiration in the same way that it controls the rate of combustion of substances in the air. Nitrogen is of more direct importance to plants, as certain genera are able to fix some of the atmospheric nitrogen through the action of bacteria, as *B. radicola*, in the root nodules of legumes. While nitrogen in the atmosphere seems to be an indifferent element and has no hygienic significance, it is a constant and important constituent of all protein matter. The amount of nitrogen dissolved as a gas in the blood and body juices increases proportionately with the pressure (P. Bert), and may lead to gas emboli, as in caisson disease.

## ARGON

Argon, discovered in 1894 by Lord Rayleigh and Professor Ramsey, is quite inert chemically; that is, it has not been made to combine with any other element. It comprises from 0.75 to 1 per cent. of the atmosphere. Argon has not been demonstrated in the body; it is apparently indifferent, and, so far as our present knowledge goes, has no hygienic significance.

## OZONE

Ozone, described by Schönbein in 1840, is rarely found in the air in greater proportions than mere traces, but it is so potent chemically that even small quantities may be of importance. At Montsouris, after years of observation, the largest quantity of ozone found in outside air

was 1 part in 700,000. Ozone may be regarded as a normal constituent, though by no means constant in air. It is generally absent in the air of large towns and cities, and almost never present in the air of inhabited rooms. It is most abundant at sea and near woods.

Atmospheric ozone is formed in nature during electric discharges, by the oxidation of phosphorescent substances; and perhaps by the respiration of plants; also by friction of large masses of water, such as the sea against the air.

Ozone consists of three atoms of oxygen instead of two, compressed into a molecule, thus:  $3 \text{O}_2 = 2 \text{O}_3$ . It is one of the most powerful oxidizing agents known, and in small amounts is exceedingly irritating; in large amounts it is fatal to life. Ozone is one of our most active bleaching agents, and in proper concentration is one of the most potent germicides known, and is used to sterilize water, to disinfect bandages, and for other purposes.

It requires at least 13 parts of ozone per million in the atmosphere to influence bacteria. Such large proportions are never present under natural conditions. Comparatively small amounts are irritating to the respiratory mucous membrane. Thus, Hill and Flack<sup>4</sup> have studied the action of pure ozone (free of contaminating oxids of nitrogen), and find it irritating in the proportion of one part per million. Exposure for two hours to a concentration of 15 to 20 parts per million endangers life. Hill and Flack conclude that there is no harm in breathing weak concentrations of ozone, such as can scarcely be perceived by a keen sense of smell.

Bohr and Maar found that any considerable concentration (even less than 1 part per million) diminishes the oxygen intake and the carbon dioxid output. The symptoms produced by exposure to ozone in addition to irritation of the mucosa, are headache, restlessness, drowsiness, depression and coma.

Since ozone in concentration of one part per million parts of air is certainly injurious, and since this amount of ozone will not destroy odors nor kill bacteria, nor purify organic matter, it has no hygienic value and should not be used as a substitute for room ventilation or to purify air in offices, schools, and other occupied spaces.

Ohlmüller<sup>5</sup> demonstrated that ozone in considerable strength was incapable of killing dry bacteria within the time limits of his tests. Jordan and Carlson<sup>6</sup> and also Konrich<sup>7</sup> found that ozone ranging from

<sup>5</sup> "Ueber die Einwirkung des Ozons auf Bakterien." *Arb. a. d. k. Gesundheits-amte*, 1893, VIII, 229.

<sup>6</sup> Jordan, E. O., and Carlson, A. J.: "Ozone: Its Bactericidal, Physiologic and Deodorizing Action," *J. A. M. A.*, Sept. 27, 1913, LXI, No. 13, Part 1, p. 1007.

<sup>7</sup> Konrich: "Zur Verwendung der Ozons in der Lüftung," *Ztschr. f. Hyg.*, 1913, LXXIII, 443.

3 to 4.6 parts per million exerts no surely germicidal action, and that the alleged effects of ozone on the ordinary air bacteria, if it occurs at all, is slight and irregular even when amounts of ozone far beyond the limit of human physiologic tolerance are employed.

Human beings are injuriously affected by amounts of ozone far less than are necessary to produce even a slight bactericidal effect. Ozone, therefore, has no place in practical disinfection of occupied places.

The exaggerated claims of the deodorizing properties of ozone are not justified. Ozone masks disagreeable odors without destroying them. In this way ozonizing machines can conceal faults in ventilation while not correcting them. These conclusions have been reached by Jordan and Carlson, Erlandsen and Schwarz, Hill and Flack, and Konrich, Sawyer, and others. The New York State Commission on Ventilation found that ozone failed to destroy body odors in the recirculated air of a school.

Recently ozonizers have been placed upon the market for the purpose of purifying the air of rooms: these must not be regarded as substitutes for ventilation. Not only may the ozone itself be harmful, but the higher oxids of nitrogen may be formed when the electric current acts upon moist air. Ozone is a poison rather than a purifier.\* See also pages 1129 and 1404.

The *tests* for ozone depend upon the fact that it oxidizes the color of tincture of guaiac, causing it to turn blue. It also acts upon potassium iodid, which turns starch a blue color due to the presence of free iodin:  $2\text{KI} + \text{H}_2\text{O} + \text{O} = 2\text{KOH} + \text{I}_2$ .

*Method* for determining the amount of ozone in air is that recommended by Baumert modified by Hill and Flack.<sup>9</sup>

Ten liters of ozonized air are drawn through a bottle containing 50 c.c. of 1 per cent. solution of potassium iodid acidified by 5 c.c. of 10 per cent. solution of sulphuric acid; 1 c.c. of 1 per cent. solution of boiled starch added, and titrated with hyposulphite solution. The hyposulphite solution is made up to contain 0.222 gm. per liter, so that 1 c.c. of the solution represents 1 part of ozone per million parts of air when 10-liter air samples are used.

## HYDROGEN PEROXID ( $\text{H}_2\text{O}_2$ )

Hydrogen peroxid may be found in appreciable traces in rain and snow. One liter of rain or snow water contains about 0.182 mg. of

\* Sawyer, W. A., Beckwith, Helen L., and Skofield, Esther M.: "The Alleged Purification of Air by the Ozone Machine," *J. A. M. A.*, Sept. 27, 1913, LXI, 13, p. 1013.

<sup>9</sup>Hill and Flack: *Proc. Roy. Soc.*, 1911, LXXXII, 404; *Jour. Roy. Soc. Arts*, 1912, LX, 344.

hydrogen peroxid. This higher oxid gives many of the reactions of ozone, being a very active oxidizing agent, and care must be exercised not to confuse them.

### AMMONIA

The ammonia in the air comes largely from the decomposition of organic matter. It is produced in sufficient quantities in a manure heap to be perceptible to the senses. Ammonia may be regarded as one of the normal constituents of the atmosphere, as it is constantly present in slight traces; it varies in distribution, more being found in the lower stratum of air near the soil. It exists both in the free state and also combined as nitrate and carbonate. Daily analysis of the air at the observatory at Montsouris for five years gave, as a mean for ammonia, 2.2 mg. per 100 cu. m. There is less after rain, because it is absorbed by the water during its passage through the atmosphere.

Albuminoid ammonia, according to Angus Smith, is a measure of the sewage of the air; that is, the amount of organic impurities, both living and dead.

### MINERAL ACIDS

The atmosphere at times contains nitric, sulphuric, and other acids. These are derived from electric discharges, but mainly from the combustion of coal and from industrial processes. Sulphuric acid or sulphates in the air, according to Angus Smith, is a measure of manufacturing activity and also of decomposition. In other words, it is part of the oxidized and, therefore, purified sewage of the air. Traces of sulphuric and sulphurous acids exist in the air. The sulphates and sulphites are usually present as ammonia salts. These substances are usually present in such small amounts that they are appreciable only when washed into rain or snow. A liter of rain water may contain from 0.7 to 2.99 mg. of sulphuric acid. More of this acid is found in the air about industrial centers than in the air over country or sea. The sulphuric acid in the air comes mainly from the sulphur in coal.

### CARBON DIOXID

Carbon dioxide ( $\text{CO}_2$ ) is a very important constituent of the atmosphere. The amount of this gas in the air is relatively small—normally about 0.03 per cent., usually expressed as 3 parts in 10,000. When we consider the great bulk of the atmosphere the total amount of carbon dioxide is very great. It is estimated that there is more carbon in the

form of carbon dioxide in the air than there is in all other forms on the earth. Formerly the amount of carbon dioxide in the air was stated as 4 parts in 10,000, but repeated analyses with improved methods have shown that the correct amount is 3 parts or slightly more.<sup>10</sup> There is apt to be more carbon dioxide in the air just above the soil than at a height of 8 or 10 feet. This is not because the carbon dioxide is heavy and settles, but because the soil air usually contains more of this gas. Air collected at great heights by balloons has just the same percentage of  $\text{CO}_2$  as air at sea level. The air over the sea contains somewhat less than air over the land. Carbon dioxide in the air comes from the oxidation of organic matter, from respiration, from fermentation, from chemical action in the soil, and from mineral springs. The exhaled breath contains about 5 per cent. of  $\text{CO}_2$ .

Even a small alteration in the percentage of carbon dioxide, either up or down, would throw out of adjustment a long-established balance, and this would alter the climate of the earth and might cause the death of all living beings. The carbon dioxide in the air is the source from which green plants with the assistance of sunlight obtain their carbon, and is thus indirectly the source of the carbon in the bodies of animals. The normal variations in the carbon dioxide of air in the open are too small to be of sanitary importance, and it is only when stagnant or inclosed air is polluted by combustion and respiration that we find accumulations which may have a bearing upon health. In narrow courts and in smoky air the free atmosphere may contain 0.7 to 0.8 per cent. In moving picture theaters the  $\text{CO}_2$  may rise to 42 and even 72 parts in 10,000. Workshops may contain from 32 to 53 parts of carbon dioxide per 10,000, and breweries as much as 5 per cent and more. Its significance varies with its source. Enormous volumes of carbon dioxide are constantly being poured into the atmosphere. Manchester adds 8,000,000 cubic meters of  $\text{CO}_2$  a day from the chimneys of industrial establishments. Even then the air of the city averages only 0.0385 per cent.  $\text{CO}_2$ , while the air of the country averages 0.0318 per cent.—a very slight difference. It is estimated that from all sources 500,000,000 tons are discharged annually into the atmosphere. The reason that the carbon dioxide does not accumulate and increase is that it is constantly removed, especially by growing vegetation. Plants absorb enormous amounts under the influence of light and chlorophyl to build carbohydrates. It has been estimated that an acre of tree land withdraws in one season about  $4\frac{1}{2}$  tons of  $\text{CO}_2$ . Much of the gas is also absorbed by water, which at ordinary temperatures takes up its own volume. The ocean acts as a great regulator to keep the amount of  $\text{CO}_2$  in the air constant.

<sup>10</sup> Average of many analyses by F. G. Benedict is 0.031. *Carnegie Publications No. 166*, 1912.

The amount of carbon dioxide produced by respiration varies with the vitality, size, and activity of the individual. During violent exercise almost ten times as much carbon dioxide may be discharged as during sleep. On the average a man discharges about 0.6 of a cubic foot of carbon dioxide per hour and a woman about 0.4 of a cubic foot. During ordinary activity a man produces, in round numbers, one cubic foot per hour. An ordinary gas jet burns about 6 cubic feet of gas per hour and produces about 3 cubic feet of carbon dioxide. Therefore, so far as CO<sub>2</sub> is concerned, a man vitiates the air less than a gas jet.

**The Amount and Function of CO<sub>2</sub> in Alveolar Air.**—Haldane and Priestley<sup>11</sup> have shown that the regulation of breathing is largely dependent on the concentration of CO<sub>2</sub> in the air cells of the lungs, that is, the alveolar air. The concentration of CO<sub>2</sub> in the arterial blood is determined by the proportion of this gas in the air cells. The nerve cells in the respiratory center are stimulated by the CO<sub>2</sub> in the blood. Fixed acids will also stimulate respiration. Thus, beta oxybutyric acid is the cause of dyspnea in diabetic acidosis. In fact, the true stimulant of the respiratory center is the hydrogen ion concentration of the blood; any fixed acid which accumulates, or any excess of carbon dioxide, will vary the hydrogen ion concentration and thus stimulate the respiratory center. Ordinarily, this stimulation is largely due to the acid base equilibrium of the blood plasma. The carbon dioxide is largely carried by the hemoglobin which absorbs the carbon dioxide as oxygen is given off in the tissues, and the process is reversed in the lungs.<sup>12</sup> The sodium bicarbonate of the blood plasma acts as a stabilizer of the hydrogen ion concentration of the blood.

The CO<sub>2</sub> which is being constantly formed in the body is carried to the lungs by the venous blood. It escapes from the blood into the air cells of the lungs and its escape is impeded or accelerated according to the resistance it meets in them. This resistance depends on the proportion of CO<sub>2</sub> in the alveolar air, since the tension of this gas in the blood can only fall as low as it is on the other side of the membrane separating the blood stream from the air cell. The arterial blood leaves the lungs with essentially the same pressure of CO<sub>2</sub> that is found in the alveolar air. In this way the alveolar CO<sub>2</sub> regulates the CO<sub>2</sub> tension in the blood and so controls the respiratory movements. This is true under normal conditions, but Haldane, Meakins and Priestley<sup>13</sup> have shown that if the oxygen in the air breathed falls to about 11 per cent., then the low percentage of oxygen stimulates the respiratory center to rapid, shallow breathing with increased pulmonary ventilation. Even

<sup>11</sup> Haldane and Priestley: "The Regulation of the Lung Ventilation," *Jour. Physiol.*, 1905, XXXII, 225.

<sup>12</sup> Buckmaster: *Journ. Physiol.*, Vol. LI, pp. 105-110; also pp. 164-175.

<sup>13</sup> *Journ. Physiology*, 1918, LII, 420-432.

at an oxygen tension of 18.1 per cent., Ellis found the respiratory volume increased.<sup>14</sup>

The breathing is so regulated as to maintain the percentage of  $\text{CO}_2$  in the alveolar air at a pressure of about 5 per cent. (5.3 to 6.3 per cent.) of an atmosphere. If the pressure falls below this, in the normal individual respiration is lessened or stopped until the loss is regained. If it goes above 5 per cent. respiration is increased until the normal is restored.

Normally, the carbon dioxide tension of the alveolar air varies between 38 and 45 millimeters of mercury or 5.3 to 6.3 per cent. If abnormal acids are present in the blood, carbon dioxide is driven off from the plasma and as the tension falls in the blood it falls likewise in the alveolar air. A low carbon dioxide tension in the alveolar air during rest therefore indicates an accumulation of fixed acids in the blood, a so-called "acidosis." If the carbon dioxide tension lies between 32 and 28 millimeters of mercury, a mild acidosis is present and below 25 millimeters of mercury the acidosis is severe.

Haldane and Douglas<sup>15</sup> found that from lying in bed to walking five miles per hour the  $\text{CO}_2$  in the alveolar air was increased twelve times, and that the alveolar ventilation was likewise increased twelve times, so that the percentage of  $\text{CO}_2$  in the alveolar air remained practically constant. Henderson<sup>16</sup> found no material change in the composition of the alveolar air on going from rest to strenuous exercise. The increased production of  $\text{CO}_2$  was perfectly compensated for by increased breathing.

There can be no doubt that there is a wide range of physiologic response on the part of the respiratory function to meet changing external as well as internal amounts of  $\text{CO}_2$ . Thus, when more  $\text{CO}_2$  is formed in the body the respiration is automatically increased in like proportion, and in this way the alveolar  $\text{CO}_2$  is kept at a uniform level of about 5 per cent. The same thing happens when we breathe an atmosphere containing an excess of  $\text{CO}_2$ . The volume of air breathed is then increased in such a degree as, if possible, to keep the  $\text{CO}_2$  in the alveolar air normal. Haldane and Priestley<sup>17</sup> found that with 2 per cent. of  $\text{CO}_2$  in the inspired air the pulmonary ventilation is increased 50 per cent.; with 3 per cent. it is increased about 100 per cent.; with 4 per cent., about 200 per cent.; with 5 per cent., about 300 per cent.; and with 6 per cent., 500 per cent. With the last the alveolar tension of  $\text{CO}_2$  is, of course, above the normal, and this fact is signified by severe pant-

<sup>16</sup> Henderson and Russell: "A Simple Method for Determining the Carbon Dioxide Content of the Alveolar Air," *Am. Jour. Physiol.*, 1912, XXIX, 436.

<sup>17</sup> Haldane and Priestley: "The Regulation of the Lung Ventilation," *Jour. Physiol.*, 1905, XXXII, 225.

ing; but up to 3 per cent. in the inspired air the increase of breathing is scarcely noticed, unless muscular work is done, when the increased internal production of  $\text{CO}_2$  calls for a still greater increase of the pulmonary ventilation. The adjustments are automatic and go on without our consciousness, unless an excessive increase of breathing is demanded.

Since even under the most favorable conditions we cannot avoid drawing back into the lungs some of the air that has just breathed out, not much hygienic importance can be attached to the slight variations in  $\text{CO}_2$  content which ordinarily occur in the air of rooms. See pages 957 and 963.

**$\text{CO}_2$  as an Index of Vitiatio.**—For years the amount of  $\text{CO}_2$  in the air has been generally adopted as the most convenient index of the total conditions which are usually prejudicial to health and comfort. The efficiency of ventilation also for years was usually determined by an estimation of  $\text{CO}_2$ .

$\text{CO}_2$  in itself is not irritating or poisonous. Large volumes may be taken in beverages or inhaled without noticeable effects. Effects are scarcely felt on the human system when the  $\text{CO}_2$  reaches 2 or 3 per cent. The result of a concentration of 2 per cent.  $\text{CO}_2$  is simply to cause an automatic increase of 50 per cent. in depth of breathing, such as occurs in moderate exercise. Respirations increase with the percentage, in depth only, until about 5 per cent., when there is distinct panting, and at 7 or 8 per cent. the dyspnea becomes distressing; and headache, nausea, and chilliness may be noted. Observations made by Professor W. G. Anderson in my laboratory show that these symptoms are more acute when the carbon dioxid is added to the air rapidly. Tolerance or second wind may be obtained in atmospheres containing even as much as 10 per cent. Animals soon die when the percentage reaches 35 or 45 per cent. in an artificial atmosphere. Man soon becomes unconscious and suffocates in an atmosphere containing 30 per cent. of  $\text{CO}_2$ .

Benedict and Milner<sup>18</sup> observed seventeen subjects kept for varying periods from two hours to thirteen days in a small chamber with a capacity of 189 cubic feet, in which the air was recirculated, but controlled chemically and physically. The  $\text{CO}_2$  was usually over 8 to 9 times normal (over 35 parts per 10,000), often over 100 parts, and sometimes 240 parts per 10,000, and yet there was no discomfort so long as the chamber was kept cool.

Pettenkoffer in 1858 proposed 10 volumes of  $\text{CO}_2$  in 10,000 volumes of air as the limit for inhabited rooms. De Chaumont (1875) found that an unpleasant odor becomes perceptible in air containing 6 volumes of  $\text{CO}_2$  in 10,000, and fixed this as the limit, which for many years has been accepted by sanitarians. It was soon learned, however, that the percentage of  $\text{CO}_2$  may rise much higher before ill effects become

<sup>18</sup> *Bull. No. 175*, U. S. Dept. of Agriculture, 1907.

perceptible. Carnelly, Anderson and Haldane in 1887 concluded that for the very crowded elementary schools a lower limit than 13 volumes was not practical. Haldane and Osborne in 1902 recommended a limit of 12 volumes for factories and workshops at the breathing level, and that when gas or oil is used for lighting the proportion should not exceed 20 volumes. The general consensus of opinion to-day is that 10 volumes in 10,000 is well upon the safe side, although, so far as  $\text{CO}_2$  itself is concerned, more might be permitted without fear. Carbon dioxid is by no means the most mischievous of the constituents of vitiated air. It is not merely a waste product. It is one of the important hormones of the body. It helps to regulate the action of the heart, influences the tonus of blood vessels, and stimulates the respiratory center.

It is certainly erroneous and unscientific to rely upon determinations of  $\text{CO}_2$  in the air of a room as the sole measure of its conditions for respiration. Carbon dioxid never accumulates sufficiently in any ordinary room to become in itself serious; further, the amount of  $\text{CO}_2$  in the air of a room gives no indication whatever of the moisture, the temperature, or the motion of the air of that room. While the amount of  $\text{CO}_2$ , then, gives us a rough index of the degree of vitiation of the air, it affords no information concerning its physical conditions, which are of special importance.

The significance of carbon dioxid upon health is further discussed on page 957.

**Methods of Determining Carbon Dioxid.**—For the ordinary purposes of a sanitary analysis it is not necessary to make an accurate analysis of the carbon dioxid in air, such as the chemical analyst or the student of metabolism would make in scientific research. As the carbon dioxid in itself is not poisonous and is only an imperfect index of other impurities, and as its significance varies with its source, sufficient information may be gleaned for sanitary purposes from methods that give results relatively comparable.

The most accurate method of determining  $\text{CO}_2$  in the air is that described by Petterson, and used in the Petterson-Palmquist, the Sonden or the Haldane apparatus. Both the Petterson-Palmquist and the Haldane methods are convenient, practical, and sufficiently accurate for all ordinary purposes. The method of Cohen and Appleyard is reasonably accurate and very convenient. The methods of Wolpert and Fitz give only rough estimates.

*Collection of Samples.*—The collection of the samples of air to be analyzed is fully as important as the actual test. The following methods may be used:

*The water siphon method*, which consists of two bottles (diameter one-third the height), volume about one-half liter, of nearly equal ca-

capacity, fitted with rubber stoppers carrying small glass tubing connected by several feet of rubber tubing with clamps. Fill one bottle completely with water, nearly free from carbon dioxid.

The pair of bottles is taken to the place from which the air is to be collected. The inlet or collecting tube may be long, so as to reach nearly to the ceiling, or short; if long, the first siphoning should be rejected to insure filling the inlet tube with the air desired. The stoppers are then exchanged and the sample taken. The air-filled bottle should be stoppered and taken to the laboratory; or the test solution may at once be added, and the bottle stoppered and shaken, noting minutes and seconds in the Cohen-Appleyard method. One bottle of water with a small reserve will serve for a number of takings before absorbing a sufficient amount of  $\text{CO}_2$  materially to influence the results. If the water is acidulated it will take up less  $\text{CO}_2$ .

*The steam vacuum method* may be used as an alternative in less accurate work. The bottles should be of about 150 c. c. capacity, made for a ground-glass stopper, but fitted with a rubber stopper. These are filled with steam from water first freed of  $\text{CO}_2$  and air by boiling for 5 minutes. The bottles are inverted and a steam jet having sufficient pressure to throw the vaporized steam at least one foot is allowed to fill the bottle for 3 minutes. Meanwhile a thin coating of vaselin is applied halfway up the sides of the stopper. This not only makes a tight joint, but facilitates removing the stopper. As soon as the collecting bottle is removed from the steam jet the stopper is instantly inserted and securely pushed in while the bottle is still in the inverted position. To test the method for completeness of vacuum hold the bottle in an inverted position under water at  $70^\circ \text{F}$ . and remove the stopper.

*Samplers* consisting of special glass tubes provided with a glass stopcock at both ends may be used to collect samples of air, particularly for the Sonden, Petterson-Palmquist, or Haldane apparatus. These samplers have a capacity of about 100 c. c.; some of them hold about 200 c. c. They must be clean and absolutely dry. The samplers are filled by means of a bulb from a Davidson syringe. Care must be taken that enough of the air to be examined is drawn through the sampler to force out all the original air it contains. Samples may be collected in duplicate, and duplicate analyses are always advisable.

*The Haldane Apparatus.*—This apparatus, shown in Fig. 86, was introduced for the determination of carbon dioxid in the case of ordinary rooms, schools, factories, etc. As the apparatus is portable, the analysis can be made directly on the spot and the carrying to and fro of samples is thus avoided, if desired. If the buret is allowed to fill while the apparatus is carried across the room, a good average sample is obtained. As it takes some seconds for the mercury to run down, this

method of taking the sample can easily be adopted, or a sampler containing the air to be examined can be connected directly by means of rubber tubing to the gas buret. In this case it is advisable to discard the first filling of the gas buret A in order to get rid of the air in the rubber tubing and connections. About 4 minutes are required for an analysis. The accuracy is about 1 part in 10,000.

The air buret A, which is enclosed in a water jacket O, consists of

FIG. 86.—PORTABLE HALDANE APPARATUS FOR SMALL PERCENTAGES OF CARBON DIOXID.

a wide, ungraduated and a very narrow graduated portion. This is divided into 100 divisions, each of which corresponds to 1 part in 10,000. The lowest division is marked 0 and the numbering is upward from this point. Any difference between a reading at or near zero and a second reading is thus shown by the scale in volumes per 10,000, there being no calculations or corrections.

The absorption pipet D is filled to the mark E with a 20 per cent. solution of caustic potash through reservoir I. The control tube G enclosed in the water jacket is used to correct for variations in the tempera-

ture of the sample during the analysis. It is connected with the potash pipet D by the tube H, which has a mark K. The pressures under which the readings are made are maintained constant by adjusting the levels of the potash solution to the marks E and K. To compensate for variations of temperature of the water jacket O, air is blown through the tube N, thus agitating the contained water.

The technic of an analysis is summarized as follows:

(1) Open the 3-way cock B to the air to be examined and raise the mercury bulb C to expel the air in the buret A. Lower the mercury bulb and hang on the adjustable rack F so that the sample is drawn in and the level of the mercury falls to near the zero mark.

(2) Open the cock M to the air for a moment and then turn it so as to connect the control tube with the potash solution in the tube H.

(3) Turn the cock B so as to connect the sample with the potash pipet D.

(4) Squeeze the rubber tube of the potash reservoir I so as to raise the potash level about an inch above the marks E and K, and see that the level of the potash alters sharply and about equally in the two tubes.

(5) Blow air through the water jacket O.

(6) Raise or lower the potash reservoir I till the potash is exactly at the mark K in the tube H.

(7) Raise or lower the mercury bulb C by means of the arrangement F till the potash is exactly at the mark E.

(8) Read off the mercury level on the scale of the buret to 0.2 of a division. (First reading.)

(9) Raise the mercury bulb, so as to drive the air into the potash pipet D; then lower it a little and raise it twice again so as to wash any carbonic acid in the connecting tubing into the pipet.

(10) Return the air to the buret A.

(11) Again blow air through the water jacket.

(12) Squeeze the rubber tubing and adjust the two potash levels at K and E, as before, and again read off the mercury level. The first reading subtracted from the second gives the amount of  $\text{CO}_2$  in volumes per 10,000.

(13) After the analysis open G to the outside air through cock M and shut off A and D by turning cock B. This will prevent fouling of the apparatus by the sucking up of the potash solution.

*The Petterson-Palmquist Method.*—This is a simplified Sonden apparatus by which the volume of  $\text{CO}_2$  in the air may be determined directly in hundredths of a per cent. by volume. The method is accurate to one part in 20,000 of air, provided care is taken with the tests.

The principle is essentially the same as that found in the Haldane or the Sonden apparatus. A measured amount of air is collected in a gas

buret. This volume of air is then transferred to an Orsat tube containing a strong solution (20 per cent.) of potash, which absorbs the  $\text{CO}_2$ . The air is then returned to the gas buret and remeasured for

FIG. 87.—PETTERSON-PALMQUIST APPARATUS.

loss in volume. Great care must, of course, be exercised that the pressure and temperature are precisely the same before and after absorption. The gas buret A, Fig. 87, is first filled with mercury by raising the reservoir E. The sample to be analyzed is then drawn into A by low-

ering E. There must always be a drop of water on the surface of the mercury and also in the compensating cylinder C. In this way the air sample is kept saturated with moisture. In reading the volumes the meniscus of the mercury is each time so adjusted that the pressure in A is exactly the same as the pressure of the air in the compensating cylinder C. This is accomplished through a differential manometer containing a drop of colored liquid (petroleum, in which azobenzol is dissolved). This manometer is connected by capillary glass tubes on one side with A and on the other side with C. After the gas pipet A is filled with the sample of air to be tested, close the stopcocks d, f, c, and g and adjust the level of the mercury in A, so that the drop of liquid in the manometer stands at zero on the scale. This adjustment is accomplished through the set screw E. In this way the air in A may always be brought to the same pressure as that prevailing in the compensator C. Since the air in both compensator and pipet is, from the beginning of the experiment, separated from the external atmosphere by closing the stopcocks f, g, and c, variations in the external atmosphere have no effect. The temperature is regulated by filling the jar with water and keeping it agitated, preferably with bubbles of compressed air.

Each analysis consists of three operations:

(1) The air is drawn in from the outside and is measured, the level of the mercury in the graduated tube being brought to the zero mark. The upper and narrower part of the scale, where each division denotes  $1/10,000$  of the volume of the pipet, is used in analysis of atmospheric air, or the ordinary air of rooms, where the per cent. of carbon dioxid is at the most not higher than 0.4 per cent. In the analysis of very impure air the lower part of the graduated tube is used, each division here corresponding to  $1/1,000$  of the whole volume. In measuring the volume of the stopcocks f, g, b, c, and d must be closed.

(2) The stopcocks d and b are opened, a is closed, and the air is passed from A to B. After one or two minutes the carbon dioxid is absorbed and the air may be brought back into A; b is then closed and a is opened.

(3) The mercury level in A is so adjusted that the index again takes its normal position. The decrease in volume is then read off on the scale.

Acidulated water may be used to expel the air from samplers into the buret of the gas analysis apparatus, if the operation is quickly done. If a refinement of accuracy is desired mercury is preferable, for even acidulated water will take up some  $\text{CO}_2$ .

*Method of Cohen and Appleyard.*—This method is based upon the fact that, if a dilute solution of lime water slightly colored with phenolphthalein is brought in contact with a sample of air containing

more than enough  $\text{CO}_2$  to combine with all the lime present, the solution will gradually be decolorized. The time necessary to discharge the color depends upon the amount of  $\text{CO}_2$  present. The amount of lime water and the volume of air being constant, the rate of decoloration varies inversely with the amount of  $\text{CO}_2$ .

Collect samples of air in clean, clear glass-stoppered bottles of half liter capacity. The sample may be collected by exhausting the air from a bottle with a pair of bellows or by completely filling the bottle with water and then emptying it at the point where the sample is to be taken. Run in quickly 10 c. c. of the standard lime water (see below). Replace the stopper; note time. Shake the bottle vigorously until the pink color disappears; again note time, and ascertain the corresponding amount of  $\text{CO}_2$  from the following table:

Time in Minutes to Decolorize the Solution	$\text{CO}_2$ per 10,000	Time in Minutes to Decolorize the Solution	$\text{CO}_2$ per 10,000
$1\frac{1}{4}$ .....	16.0	$3\frac{1}{2}$ .....	7.0
$1\frac{1}{3}$ .....	13.8	4 .....	5.3
$1\frac{1}{2}$ .....	12.8	$4\frac{1}{4}$ .....	5.1
2 .....	12.0	5 .....	4.6
$2\frac{1}{4}$ .....	11.5	$5\frac{1}{4}$ .....	4.4
$2\frac{3}{4}$ .....	8.6	$6\frac{1}{4}$ .....	4.2
$3\frac{1}{4}$ .....	7.7	$7\frac{1}{2}$ .....	3.5

*Standard Lime Water for Testing  $\text{CO}_2$ .*—The solution used is a dilute solution of lime water colored with phenolphthalein. To freshly slaked lime add twenty times its weight of water in a bottle of such size that it is not more than two-thirds full. Shake the mixture continuously for 20 minutes, and then allow it to settle over night or until perfectly clear. The resulting solution is the stock lime solution, or “saturated lime water.” If made in the manner indicated, each cubic centimeter of it will be very nearly equivalent to 1 milligram of carbon dioxide.

If, however, it is desired to know the strength of it more exactly, it may be determined by titrating with a standard acid.

To a liter of distilled water add 2.5 c. c. of phenolphthalein (made by dissolving 0.7 gram of phenolphthalein in 50 c. c. of alcohol, and adding an equal volume of water). Stand the bottle of water on a piece of white paper and add, drop by drop, saturated lime water till a faint color persists for a full minute. Now add 6.3 c. c. of saturated lime water, quickly cork the bottle, and avoid contact with the  $\text{CO}_2$  of the air.

For accuracy in testing air which is high in carbon dioxide, it is found advantageous to use a solution twice as strong as the above. This double solution is prepared in precisely the same way, using 5.0 c. c. of the phenolphthalein solution and 12.6 c. c. of the “saturated lime water.”

While this procedure does not give an exact volume of solution, it is

believed to be the best for the preparation of this dilute test solution, since it obviates the necessity for pouring the prepared solution from the measuring-flask into the bottle in which it is kept: 12.6 c. c. of the stock lime solution is added rather than 10 c. c., in order to keep the values obtained with the resulting solution more nearly comparable with the older values calculated on the supposition that 10 c. c. of "saturated lime water" was equivalent to 12.6 milligrams of carbon dioxide (Richards and Woodman).

*Methods of Wolpert and Fitz.*—These are rough methods for determining carbon dioxide, and while not quite as accurate as the Cohen and Appleyard method, are useful because of their simplicity and convenience. The Wolpert tester gives better results than that of Fitz.

The volume of air that must be brought into contact with a definite quantity of lime water in order to neutralize all the lime is taken as a measure of the  $\text{CO}_2$  in the air. The quantity of lime water and the time of reaction remaining constant, the amount of  $\text{CO}_2$  varies inversely as the volume of air. The apparatus consists of graduated shakers (see illustration), and a pipet for measuring 10 c. c. of the standard lime water solution. See page 883.

In using both the Wolpert and the Fitz apparatus care should be taken that the finger used to close the end of the tube is clean, since on a warm day the free acid in the perspiration might vitiate the results. This error may be obviated by using a rubber stopper or cap.

*The Wolpert Air Tester.*—In using this apparatus first remove the plunger and introduce 10 c. c. of the standard lime water solution (see page 883) into the graduated cylinder. Immediately insert the plunger and press it to the surface of the lime water. Next, withdraw the plunger to the 50 c. c. mark. Place the finger or rubber cap over the end of the piston

FIG. 88.—WOLPERT AIR TESTER.

and shake vigorously for 30 seconds. Remove finger or cap; press the plunger again to the surface of the liquid, withdraw it to the 50 c. c. mark, and shake, continuing this process until the color is discharged.

Air in c. c. Used	CO <sub>2</sub> per 10,000	Air in c. c. Used	CO <sub>2</sub> per 10,000
30.....	28	91.....	9
36.....	22	103.....	8
46.....	18	117.....	7
58.....	14	138.....	6
69.....	12	165.....	5
82.....	10	207.....	4

Each withdrawal of the plunger admits 40 c. c. of air to the cylinder, and from the total volume of air thus admitted the approximate amount of air necessary to discharge the color is determined. A more accurate estimation of the amount of air necessary to decolorize the lime solution can be obtained by repeating the process and admitting a smaller amount of air to the cylinder the last time the plunger is withdrawn. From the total amount of air used in the second test, the amount of CO<sub>2</sub> can be determined from the above table.

A more convenient but less accurate method of using this apparatus is to put 2 c. c. of the lime water into the cylinder, insert the plunger to the line marked "extremely bad" (4 per cent.) and shake for one minute. Then if the color is not discharged withdraw the piston a little farther and shake again, and so on until the position of the plunger, when the color is gone, can be determined. From this the percentage of CO<sub>2</sub> can be read off directly from the figures on the left of the cylinder.

*Fitz Air Tester.*—This apparatus consists of a tube closed at one end, and graduated for a distance of 20 c. c. Another tube smaller in size and open at both ends, slides within the graduated tube by means of a rubber collar. This rubber collar should be moistened in order that the inner tube may slide readily.

Press the inner tube down to the bottom of the larger one and measure into the apparatus 10 c. c. of the standard lime water solution (page 883). Withdraw the inner tube up to the "tare mark" (T) which corresponds to the 5 c. c. mark. The bottom of the inner tube serves as the index. Now quickly close the end of the smaller tube with the finger; hold the apparatus horizontally, and shake it vigorously for 30 seconds.

The amount of air that has thus been brought in contact with the

FIG. 89.—FITZ AIR TESTER.

solution is 30 c. c. Remove the finger, again press down the small tube to the bottom of the larger, and draw it to the 20 c. c. mark. Shake the apparatus again for 30 seconds. The additional amount of air brought in contact with the solution is 20 c. c. Repeat the shaking, using 20 c. c. of fresh air each time until the pink color is discharged. A slight trace of color may be ignored. The amount of  $\text{CO}_2$  corresponding to the total number of c. c. of air used will be found in the table on page 885.

## CHAPTER II

### PRESSURE, TEMPERATURE, AND HUMIDITY

#### PRESSURE

**Normal Atmospheric Pressure.**—The pressure of the atmosphere at sea level is 15 pounds to the square inch, or, as indicated in the barometer, it will maintain a column of mercury 30 inches or 760 millimeters. A man of average size living at sea level is exposed to a total pressure of about 34,000 pounds—more than 15 tons. This great pressure must evidently have physiological importance. All the tissues and fluids of the body are subjected to this pressure and are in equilibrium with it. The interchange of gases on which life depends is largely a phenomenon of atmospheric pressure. The pressure of the air also keeps the heads of the bones in their sockets without muscular action, and doubtless performs other functions less obvious. The small variations in pressure such as occur day by day at sea level have no evident physiological effects.

**Diminished Atmospheric Pressure.**—A diminution in atmospheric pressure is equivalent to breathing rarefied or diluted air. This is met with mainly in aviation. The symptoms are due to the low partial tension of the oxygen. If oxygen gas is added to the inspired air at low barometric pressures, no discomfort is experienced. The dangers of rarefied air are those of oxygen deficiency. Acidosis attends the severer stages. An adaptation response takes place under these conditions; thus, the acidosis increases the rate of breathing; and the number of red blood cells increases, thus increasing the oxygen carrying capacity of the blood. The most important physiological effects of diminished atmospheric pressure are due to a diminution in the amount of oxygen absorbed, hence the breathing is deeper and the pulse rate quickened. As the altitude increases there is a lowered tension of oxygen in the alveolar air and a diminished tension of carbon dioxide. While the rate of respiration may be variously influenced in different circumstances, the depth of respiration is almost invariably increased. This of itself not only facilitates the oxygen supply, but also increases the elimination of carbon dioxide.

Formerly a great compensatory increase in the number of red blood cells was believed to take place as a result of prolonged residence in high

altitudes. Thus, assuming the average number of red blood cells per cubic millimeter at sea level to be about 5,000,000, at Davos (elevation 1,560 meters) the number of red blood cells averages 5,500,000 to 6,500,000. At Cordilleras (altitude 4,392 meters) the average number of red corpuscles is 8,000,000. A similar change in the blood has been produced by keeping rabbits and guinea-pigs in rarefied air at sea level. According to Bürker, only a comparatively small increase takes place, amounting to 4 or 5 per cent., at altitudes of five or six thousand feet. The same moderate results have likewise been noted lately for much higher altitudes. Gregg, Lutz and Schneider<sup>1</sup> recently showed that where barometer pressure is rapidly reduced, as in aviation, there is a response by increased hemoglobin in the blood usually within twenty minutes.

At a height of 18,000 feet the pressure of the atmosphere is only half the pressure at sea level, thus:

Altitude	Height of Barometer
0 foot.....	30 inches
910 feet.....	29 "
1,850 ".....	28 "
2,820 ".....	27 "
3,820 ".....	26 "
4,850 ".....	25 "
5,910 ".....	24 "
7,010 ".....	23 "
8,150 ".....	22 "
9,330 ".....	21 "
10,550 ".....	20 "
13,170 ".....	18 "
16,000 ".....	16 "
18,000 ".....	15 "

"The highest dwelling place continuously occupied is the Observatory El Mirti, in the Andes, at 5,880 m. The Observatory at Arequipa is at 6,100 m. Thok djalung is a village in the Himalayas at 4,980 m. In Peru, Bolivia, and Northern Chili a very large part of the population live above 3,000 m. Potosi, which has numbered 100,000 inhabitants, is at 4,165 m., Cerro de Pasco at 4,350 m., the mines of Villacota at 5,042 m., the railway from Callao to Oroya culminates in a tunnel at 4,760 m., almost the height of Mont Blanc. An annual fair is held at Gartok, at 4,598 m., in the Himalayas, to which thousands annually come." <sup>2</sup>

It is evident that man may become adapted to breathing a rarefied air at great heights, which would overcome persons if the change were made suddenly from sea level. Linhard actually resided for 26 days in a pneumatic cabinet, becoming "acclimated" gradually to a reduced barometric pressure of 450 mm. at which he lived for two weeks.

<sup>1</sup> Gregg, H. W., Lutz, B. R., and Schneider, E. C.: "Compensatory Reaction to Low Oxygen." *Am. Jour. Physiol.*, 1919, pp. 302-325.

<sup>2</sup> Leonard Hill: "Recent Advances in Physiology."

*Mountain Sickness.*—The symptoms produced by a marked diminution in atmospheric pressure vary with circumstances. The effects are increased by cold, active muscular exertion, or improper clothing. The noticeable symptoms are increased depth and rapidity of respiration and acceleration of the pulse, noises in the head and dizziness, impairment of the senses of sight, hearing, and touch, dullness of the intellectual faculties, and a strong desire to sleep. Sudden changes to rarefied atmosphere cause syncope, weakness, dyspnea, dizziness, and nausea. These threatening symptoms sometimes go by the name of mountain sickness. Bert and Journet believe this condition is due to lack of oxygen and the symptoms may, in fact, be relieved by adding oxygen to the air inspired. It is now clear that it is not the reduced barometer but the reduced partial tension of the oxygen which causes the symptoms.

Bert kept a bird alive in oxygenated air, even though the pressure was reduced to less than 0.1 of an atmosphere. Kronecker concludes that mountain sickness is caused by a congestion of the lungs, impeding the flow of blood through them. Mosso and his followers attribute the physical disturbances of a reduced atmospheric pressure to the fact that the blood loses carbon dioxid more quickly than it loses oxygen, and attributes mountain sickness to this decrease of carbon dioxid in the blood (acapnia). Cohnheim believes there is a concentration of the blood at high altitudes; in fact, insignificant increases have been found by competent observers. The climate in high altitudes is always dry and evaporation proceeds rapidly. As a result individuals lose water more readily than at lower levels. If this explanation is tenable, an increase in corpuscles and hemoglobin content are in no wise the expression of a lack of oxygen, but are rather the outcome of the increased evaporation under the altered conditions of climate. The increased number of red blood cells in the peripheral circulation probably represents an outpouring from blood forming tissues.

Douglas, Haldane and Henderson<sup>3</sup> showed that "acclimatization" occurred in a few weeks on Pike's Peak, and believed that at least three factors operated in this adaptation: The cells of the alveoli of the lungs acquired the power of exchanging oxygen and CO<sub>2</sub> more vigorously for the same gaseous pressures than ordinarily; the alkalinity of the blood had changed so as to stimulate the respiratory center with a less amount of CO<sub>2</sub>; and the hemoglobin had increased so as to supply the tissues more readily with the needed oxygen.

The limit at which life may be sustained is about 26,000 feet, at which height consciousness is lost.<sup>4</sup> At this height the barometric pres-

<sup>3</sup> Phil. Trans. of the Roy. Soc. of London, 1913, Ser. B., CCHII, 185.

<sup>4</sup> The aviators, Fleming and Steyer, in June, 1911, attained an elevation of 8,910 meters, but experienced grave symptoms which urgently called for the use

sure of the air is 251 mm., which represents a pressure of oxygen of 52, which is the equivalent of 6.8 per cent. oxygen at sea level. P. Bert remained 20 minutes in a pneumatic chamber with a pressure of only 248 mm. without serious inconvenience.

**Increased Atmospheric Pressure.**—While man is often exposed to rarefied air, he is seldom subjected to increased pressure except under artificial conditions, such as in diving bells, diving suits, and caissons. The increase in atmospheric pressure in the deepest mines has little physiological significance. Divers and workers in caissons are not subjected to more than about  $4\frac{1}{2}$  atmospheres, and work under such pressure for only a few hours at a time. When a diving bell is lowered 10 meters into the water the air contained in it is compressed to one-half its original bulk, and the pressure of the air is accordingly doubled. Each 10 meters' depth means an additional pressure of one atmosphere. At a depth of 30 meters, about 100 feet, a diver is exposed to a pressure of 4 atmospheres or about 60 pounds per square inch. Bert exposed dogs to a pressure of 10 atmospheres, and then slowly released them without harm.

The physiological effects of an increased atmospheric pressure are mainly due to an increase in the amount of atmospheric gases (especially nitrogen) which are taken up by the blood, and also an increase in the chemical absorption of oxygen by the blood. The serious consequences usually result from too rapid decompression. The nitrogen is absorbed by the tissues, especially by fat and lipoid tissues contained in the nervous system. As the pressure is released gas bubbles form. Hence corpulent persons are more liable to suffer than lean; those with sluggish circulation suffer most. Gradual decompression gives a chance for the gas to escape from the lungs and be expelled without the production of gas bubbles.

*Caisson Disease.*—The effects produced by compressed air in caissons are: (1) those caused when the men are undergoing pressure, and (2) during or after decompression.

The symptoms produced by an increase of atmospheric pressure are a slowing of the respiration, which is evidently compensatory, but on account of compression of intestinal gases the respirations are deeper; the pulse is slower, and evaporation of water-vapor hindered. The voice may be altered; pains in the ear are common, due to pressure upon the drum, and may be obviated by swallowing air and thus passing it up the eustachian tube into the middle ear. Sometimes the ear drum ruptures; headache and dizziness may also occur. During compression the blood keeps absorbing the gases of the air until the tension of the gases

of oxygen inhalations. With the aid of oxygen aviators have flown above 30,000 feet—nearly six miles. Major R. W. Schroeder in 1918 reached an altitude of 36,020 feet.

in the blood becomes equal to that in the compressed air. As soon as this equilibrium has been attained relief from immediate troubles is secured.

It is during and after decompression that the greatest danger to health and even risk of life occur. The most frequent symptom is excruciating pains in the muscles and joints, called by the workmen "bends." These pains may continue for a few hours or for two or three days. Occasionally there is bleeding at the nose; also severe abdominal pain, and vomiting, nausea, vertigo, dyspnea, and unconsciousness. Death may result from internal hemorrhage, or paralysis may ensue—the so-called diver's palsy.

The effects of increased atmospheric pressure and too rapid decompression were carefully studied by Paul Bert in 1878, who showed that the lesions are caused by the escape of gases of the atmosphere which have been taken up in excessive amounts, and are released in the blood and tissues when the pressure is diminished. The blood vessels may contain gas emboli, which may lodge in vital parts and cause sudden death, or the delicate capillaries may break, leading to hemorrhages with resulting paralysis. Air emboli may be distressing or dangerous if they occur in the labyrinth of the ear, in the spinal cord, in the brain, or in the heart or other vital parts.

The prevention of caisson disease consists in gradual decompression. Sometimes the symptoms come on several hours after the workman has left the caisson. As soon as symptoms come on the workman should at once be hurried back into the compression chamber until equilibrium between the internal and external pressures is restored. He may then be allowed to pass through the decompression chambers, but very gradually. A medical air-lock should be provided at the works, well heated, and furnished with bunks and emergency supplies.

**Barometers.**—The pressure of the air is measured by means of barometers, the principles of construction and use of which are so well known that they do not require special description.

## MOVEMENTS OF THE ATMOSPHERE

Moving air is necessary for the maintenance of health and is a prime requisite of good ventilation. The motion of the air serves the twofold purpose of bringing us a fresh supply and taking away the sewage-polluted air from our immediate vicinity. Moving air also favors evaporation and helps to prevent heat stagnation by keeping the temperature within normal limits. Paul, Heymann, and Erelentz, in Flügge's laboratory, and also Leonard Hill in England, emphasized the importance of moving air in assisting the heat regulation of our body.

They believe that this is a much more important function of moving air than simply the bringing of fresh air or the carrying away of the products of respiration. In still air the body soon becomes surrounded by a warm, moist aërial envelope which causes an overheating of the surface of the body and results in the familiar symptoms of "crowd poisoning." In a still atmosphere we are soon surrounded by a blanket of stagnant and impure air, whether indoors or outdoors.

Much of the benefit of mountain, seaside, and other health resorts is attributable to the breezes that blow almost continuously at such places. The health of large cities located upon the seacoast or the shores of great lakes is favored by the quantities of moving air with which they are frequently flushed. A healthful climate is always a breezy climate—within reasonable limits. Much of the benefit of driving, of fanning, and of rocking-chairs is due to the motion of the air thus engendered.

If the air in a poorly ventilated room can be kept in motion, say with an electric fan, many of the ill effects of a vitiated atmosphere are avoided, for the products of respiration are diluted, and evaporation and heat interchange are favored. Thus, Leonard Hill placed eight students in a small sealed chamber which held about three cubic meters. He states that "at the end of half an hour they had ceased laughing and joking and their faces were congested. The carbon dioxid had gone up to 4 or 5 per cent. Three electric fans were then turned on, which merely whirled the air about just as it was. The effect was like magic; the students at once felt perfectly comfortable, but immediately the fans were stopped they again felt as bad as before." The relation of moving air to temperature and moisture, with reference to ventilation, is further discussed on page 960.

In nature the atmosphere is kept in almost constant motion as a result of differences in temperature. Thus, the hotter air in the tropics rises and divides into two currents, which flow toward the north and south, while heavier, colder air rushes along a lower level from the north and south to take the place of the lighter currents. The cold currents from the poles are known as the trade winds, and the upper, warmer currents to the poles as the antitrades. The upper currents to the poles run northwest and southwest; while the lower currents from the poles run northeast and southeast.

The chief cause of periodic winds, such as daily sea breezes and monsoons, is the difference in the heating of the air above land and above sea. On a small scale the same principle is seen at play in theaters, churches, cathedrals, and public buildings. The great mass of people crowded together heats the air about them and it ascends; cool air rushes in from the aisles to take its place, hence the almost unavoidable drafts in such places.

The velocity of air currents is customarily measured by means of

recording anemometers. These instruments require a considerable velocity of air and should never be used without a carefully prepared table of corrections whereby their readings may be adjusted.

It often becomes desirable in sanitary investigations, particularly in studies of ventilation, to determine the strength and direction of currents of air which are too delicate to be measured by means of anemometers. Lighter candles will show the direction of slight air currents, the flame being deflected in the direction in which the current is moving. More delicate than this is the method of noting the course taken by smoke from a joss-stick, cigarette, or cigar.<sup>5</sup>

When a current of air at the temperature of 55° to 60° F. moves at a rate of one mile per hour, there is no perceptible draft. The rate of movement in relation to our perception is as follows:

Air moving at 1.5 feet per second—1.0 mile an hour—imperceptible.  
 Air moving at 2.5 feet per second—1.7 miles an hour—barely perceptible.  
 Air moving at 3.0 feet per second—2.0 miles an hour—perceptible.  
 Air moving at 3.5 feet per second—2.3 miles an hour—draft.

The movement of warm air is less perceptible than the movement of cool air.<sup>6</sup>

## TEMPERATURE OF THE AIR

The temperature of the air depends mainly upon solar and terrestrial radiation. The air absorbs vast quantities of heat from the sun, and as the heat of the earth is radiated into space a certain amount is again absorbed by the atmosphere. Accordingly, the air both keeps the heat out and keeps it in. It makes the days cooler and the nights warmer. "It is a parasol at noon and a blanket at night." Except for it there would be much more violent changes in temperature (Macfie).

The power of the air to absorb heat and to store heat depends largely on its humidity; that is, on the amount of water vapor it contains, for water vapor is opaque to heat rays. The water vapor is also a great reservoir of latent heat. When water evaporates a tremendous amount of latent heat is carried up into the atmosphere with it and again becomes actual heat when the vapor condenses. The quantity of heat thus stored up in water vapor is almost incredibly great.

Air expands  $\frac{1}{491}$  of its volume for each degree rise of temperature; air at 32° F. and 30 inches barometric pressure is usually taken for unit of volume. A cubic foot of dry air at 32° F. and 30 inches barometer weighs 566.86 grains; at any other temperature, therefore, its weight can be ascertained by dividing by its increased volume.

<sup>5</sup> For a further discussion of this subject see "Air Currents and the Laws of Ventilation." by W. N. Shaw.

<sup>6</sup> For Drafts see page 248.

The temperature of the air has a very important bearing upon health. Man has an almost incredible power of adapting himself to wide variations of temperature. Workers in foundries have sometimes to endure a heat of  $250^{\circ}$  F. and even higher for short periods of time. Temperatures of  $-75^{\circ}$  F. are met with in polar expeditions. This is a range of at least  $325^{\circ}$  F. The reason that man, as well as other animals, is able to maintain a constant body temperature when exposed to such great variations of atmospheric temperature, is due not only to the physiological mechanism which regulates heat production and elimination, but to the layers of air immediately in contact with the skin. We wear clothes to protect ourselves from external heat or cold, but still more do we wear air for that purpose. That is why very high temperatures are better borne when the air is in motion, which facilitates evaporation, than when the air is still, while extremes of cold are better borne when the air is still, for then we become clothed in a warm blanket of air. The effect of heat upon health, however, cannot be considered alone, for it depends on the humidity as well as on the movement of the air. Extremes of heat and cold are much more trying when the air is humid than when the air is dry.

The direct action of heat alone as a cause of infant mortality has been greatly underestimated. The harmful effects of heat must not be measured so much by the maximum or even the mean temperatures of the outside air, but by the indoor temperatures. Indoor temperatures may continue high in spite of remissions in the temperature of the external air. The lethal effects of heat upon infants, and adults, too, are increased by the still, moist air found in overcrowded, narrow streets, and poor ventilation of houses.

Exposure of the body to dry, cold air has an effect similar to a cold bath, that is, there is an increased loss of bodily heat, followed by a demand for more. This demand is met by increased oxidation of tissue, metabolic processes become more active, and there is improvement in nutrition. It stimulates the chemical mechanism of the body for the regulation of bodily heat. In this way cold acts as a stimulant and tonic.

It is of first importance that the arrangements for heating rooms, offices, schools, etc., should be so regulated that the temperature never exceeds  $21^{\circ}$  C. ( $70^{\circ}$  F.); especially should this control be exercised in public rooms, such as schools, etc. As a rule, the temperature of heated rooms should be  $17^{\circ}$  to  $20^{\circ}$  C. ( $62.6^{\circ}$  to  $68.2^{\circ}$  F.) or under. Periodic variations of temperature are as desirable inside of buildings as in the outside temperature. The temperature of the air influences the temperature of the body, and also the general status of the vasomotor mechanism. Experiments clearly indicate that in the daily life of the school and factory the overheating of air seriously affects both health and efficiency. The atmospheric temperature also has a direct effect on

diseases of the respiratory tract. Hill and Muecke,<sup>7</sup> in England, and the New York State Commission on Ventilation<sup>8</sup> have shown that in going from a hot room to a cold room, the membranes of the nose became paler and less moist, while the inferior turbinates contract. Such an action may in part account for the well known seasonal prevalence of infections of the respiratory tract in the winter weather.

The effect of temperature upon health is so closely interwoven with humidity that this relationship is discussed on page 904.

**Methods of Recording Temperature.**—*Mercurial or bimetallic thermometers* are best suited to take the temperature of the air. The most accurate mercurial thermometers for this purpose have an elongated bulb of mercury at one end and a ring at the other, through which a cord can be tied; the scale should be etched upon the glass. A good thermometer of this type generally is accurate to about one-half to one-fifth of a degree. Thermometers placed upon a backing of metal, card, or wood, with the scale painted upon the backing, are more ornamental than accurate. They usually possess a decided lag and are, therefore, not trustworthy. Thermometers should be suspended freely in the atmosphere or at least placed in a current of air sufficient to insure good ventilation about the mercury column.

*Registering thermometers* are of two principal types: those which record maximum and minimum temperatures, and those which make a continuous record of the changes of temperature that occur.

The maximum and minimum temperatures furnish but limited information, and, as such self-recording thermometers are almost invariably mounted upon a backing, they consequently have a considerable lag. They are only dependable where fluctuations in temperature are not rapid. Under these circumstances they may be used to record the highest and lowest temperatures.

For an intelligent understanding of the sanitary condition of any room or inclosed space neither single determinations nor maximum and minimum records are sufficient. Recording thermometers should be placed at various selected points and records should be obtained covering a period of several days. The best type of recording thermometers depend upon the movements of bimetallic bars, so arranged that as they contract and expand they cause a penpoint to bear upon a moving paper scale, and so leave an ink trace. The clockwork is generally wound up for a week, for which period the paper scale is also adapted.

The temperature of the wet bulb thermometer should always be taken

<sup>7</sup> *Lancet*, 1913, CLXXXIV, 1291.

to determine the drying and cooling (Psychrometer and Kata-thermometer). Methods of recording temperatures with the Kata-thermometer, see page 907.

## HUMIDITY

**Aqueous Vapor.**—Water in its gaseous state is always present in the atmosphere. Water vapor is the most variable of the normal constituents of air, and also one of the most important, on account of its influence upon health. It is usual to consider water vapor apart from the other gases of the atmosphere, although it is just as much a gas as oxygen or nitrogen, and conforms to the general laws that govern the behavior of gases. Unlike other gases present in the air, water vapor condenses at comparatively low temperatures. As water vapor weighs only about three-fifths as much as air, dry air is heavier than moist air under equal conditions of temperature, pressure, etc. It is customary to speak of air "holding" water vapor. As a matter of fact, the air has nothing to do with it, for it should always be clearly observed that the presence of water vapor in any given space is independent of the presence or absence of air in the same space. The amount of aqueous vapor which a space contains depends entirely upon the temperature and not upon the presence of the pressure<sup>9</sup> of the air. At 32° F., for instance, the air can "hold" 1/160 of its weight of water vapor, at 59° F. 1/80 of its weight, at 86° F. 1/40 of its weight. Roughly, every 27° F. increase of temperature doubles the amount of water vapor the air can hold in proportion to its weight. In this way the heat of the atmosphere is self-protective, for it loads the air with water vapor, which in turn absorbs much of the heat. The latent heat is again given off on condensation. The actual amount of water vapor which the air can hold at different temperatures is shown in the following table:

A cubic foot of air can hold at		
10° F. ....	1.1	grains
20° " ....	1.5	"
30° " ....	2.1	"
40° " ....	3.0	"
50° " ....	4.2	"
60° " ....	5.8	"
70° " ....	7.9	"
80° " ....	10.0	"
90° " ....	14.3	"
100° " ....	19.1	"

<sup>9</sup> A high barometer retards evaporation, while a low atmospheric pressure accelerates it. All volatile liquids evaporate instantly in a vacuum. The rate of evaporation varies with temperature and pressure, but a given space will ultimately hold the same amount of gas independent of the presence and pressure of other gases.

As the temperature rises in arithmetical progression the power to retain vapor increases with the rapidity of a geometric series having a ratio of two.

FIG. 90.—DIAGRAM SHOWING ABSOLUTE HUMIDITY IN GRAINS AT DIFFERENT TEMPERATURES.

The amount of water vapor in the air may be expressed either by:  
 (1) its *vapor tension*. The tension of the water vapor in the air is expressed in inches or millimeters of mercury. If a drop of water is placed in a vacuum, say in a barometer tube, some of the water vaporizes

and the mercury is depressed, owing to the tension of the water vapor. The amount that evaporates, as well as the tension, depends upon the temperature. (2) Its weight per unit volume of air, i. e., the *absolute humidity*; and (3) the ratio of the amount of water vapor in the atmosphere to the amount it could hold at the temperature in question if saturated; that is, the *relative humidity*. Complete saturation of the air with moisture is stated at 100, and lesser amounts by percentages. (4) The amount of water vapor in the air may also be found from its *dew-point*. The dew-point for any temperature and humidity is the temperature to which the air may be cooled when precipitation takes place.

The vapor tension or the absolute humidity indicates how much water vapor the air contains, while the relative humidity is an expression of how much vapor it might contain. The amount of water vapor which air can hold when saturated at different temperatures has been calculated and recorded in Glaisher's hygrometric tables.<sup>10</sup> It is, therefore, very easy, by referring to these or to the tables in the U. S. Weather Bureau—*Bulletin No. 235*—to calculate the relative humidity if we know the actual humidity or the dew-point or *vice versa*.

The amount of moisture which out-of-door air ordinarily contains varies from about 30 per cent. or less to saturation.

In meteorological tables, giving climatic particulars of any town or locality, the relative humidity is usually stated; but it should be noticed that the relative humidity bears no constant relationship to the absolute humidity. As the relative humidity varies greatly throughout the day, and as the readings are not always taken at the same time of day in different localities, it at once becomes evident that comparisons are not reliable. In fact, a moist or dry climate cannot be predicted from the relative humidity. Thus, the mean relative humidity of Davos is as high as 79 per cent., whereas it is generally known that the climate at Davos is dry. On the other hand, in Egypt the average relative humidity is very low, although this country is known to have a moist climate. This is for the reason that the humidity readings in Egypt are taken from 10 A. M. to 6 P. M., and vary from 30.5 per cent. at Assouan to 51.7 per cent. at Menahouse. As a matter of fact, the relative humidity in Egypt decreases from 100 per cent. at dawn to 22 per cent. at noon, and may be quickly altered to the extent of 50 per cent. by a warm wind. The humidity, therefore, through the hot, sunny daytime is not a measure of the climate, so far as moisture and dryness are concerned.

In England the relative humidity averages 75 per cent. In California it drops from 100 per cent. at dawn to 22 per cent. at noon. A

<sup>10</sup> The standard hygrometrical tables in use the world over are those prepared by Mr. James Glaisher, F. R. S., of the Royal Observatory, Greenwich, England.

hot wind, by increasing the capacity of the air for moisture, may also lower the relative humidity very quickly. Thus, the Föhn wind when it reaches the Riviera lowers the relative humidity 50 to 60 per cent. in an hour or two. The mean relative humidity of Denver for the year is only 42 per cent., at San Diego, on the coast, 72.9, at Los Angeles, a few miles inland, 66.6. In the heart of the Libyan desert the relative humidity may be as low as 9 per cent. At the seaside daily variations in humidity are less than inland (Macfie). The air in forests is 10 or 20 per cent. more humid than air in the open. There may be a very great difference in the relative humidity of outside cool air and of air in a closed heated room, in that the latter may be very much drier.

So far as the effect of humidity upon health is concerned Dr. Huggard well states: "The really essential point is not the amount of moisture, relative or absolute, that is present, but the amount that can still be taken up. This varies enormously with the same degree of relative humidity at different temperatures, as the following table from Renk will show:

*Amount of vapor that can still be taken up at different temperatures and the same relative humidity*

Temperature	Relative Humidity	Absolute Humidity Grams per Cubic Meter	Grams of Vapor That Can Still be Taken Up
	Per Cent.		
-20° C.....	60	0.638	0.426
-10° C.....	60	1.380	0.920
0° C.....	60	2.924	1.950
10° C.....	60	5.623	3.749
20° C.....	60	10.298	6.866
30° C.....	60	18.083	12.056

We see by this table that the same expression, 60 per cent. relative humidity, might be applied to air capable of taking up 0.426 gram or 12.056 grams of vapor, and thus the expression as a measure of the drying capacity of the air is obviously misleading.

Dr. Huggard gives a second very instructive table, the obverse of the above:

Temperature	Relative Humidity	Vapor: Grams per Cubic Meter	
		Present	Capable of Still Being Taken Up
	Per Cent.		
3° C.....	0	0	6
10° C.....	36	3.4	6
15° C.....	53	6.8	6
20° C.....	65	11.2	6
25° C.....	73	16.9	6
30° C.....	80	24.1	6

We see from this second table that air with relative humidities of 0, 36, 53, 65, 73, and 80 per cent., and containing quantities of water vapor varying between 0 and 24.1 grams per cubic meter, are all capable of further taking up exactly the same amount of vapor. Again the expression of relative humidity is misleading.

When the relative humidity reaches 80 to 85 per cent., moisture condenses and begins to show upon objects in rooms. This influences natural ventilation through porous building materials.

There may be a very marked difference between the humidity of indoor and outdoor air, owing in part to the condensation of moisture, especially in winter, upon the cold walls and windows.

The difference between external and internal humidities depends largely upon the temperature of the surfaces in the room. These surfaces, though apparently dry, may, in fact, hold moisture in large quantities; the walls and ceilings may contain more water than all the air in the room. Ordinarily there is a continual exchange of moisture between the air and the room surfaces. In this way the walls serve as a compensating reservoir to help maintain the humidity of the air approximately constant. Cold walls, cold windows, and cold surfaces generally condense the moisture from the air so rapidly that great difficulty is experienced in raising the relative humidity of the air of a room under these circumstances.

The humidity in the air is influenced by altitude. The higher we go the colder and rarer the air becomes, therefore, it contains less moisture. Its absolute humidity, therefore, decreases. Half of the total water vapor of the atmosphere is below 2,000 meters. On the other hand, the relative humidity shows no regular change with change of altitude. Clouds do not necessarily imply high relative or absolute humidity of the lower atmosphere. Rainfall also gives only a very general indication of the humidity of the atmosphere. A place with high rainfall may have low absolute and relative humidity, and *vice versa*; that is, a rainy district is not necessarily a damp district, so far as the atmosphere is concerned.

Dew also bears no constant relationship to the humidity of the atmosphere, for a clear sky and a dry atmosphere favor its formation. Air containing mist is obviously moist.

**Methods of Determining Humidity in the Air.**—The amount of water vapor in the air may be determined either by (1) weighing, (2) psychrometers or hygrometers, (3) the dew-point.

*Weighing.*—The amount of moisture in the air may be determined by passing a given volume of air through a tube or flask containing an hygroscopic substance, such as calcium chlorid or sulphuric acid. If sulphuric acid is used small flasks are filled with pieces of pumice which have been heated to a high temperature over a Bunsen burner, and

dropped white hot in concentrated sulphuric acid; removed, and quickly drained.

The increase in weight represents the amount of moisture in the volume of air passed through the flasks, or the absolute humidity. Knowing the temperature of the air, it is then easy to determine the relative humidity by reference to tables of maximum water capacity for certain volumes of air at varying degrees of temperature.

*Psychrometers.*—The most convenient of all methods for measuring atmospheric moisture is to observe the temperature of evaporation, that is, the difference between the temperatures indicated by wet and dry bulb thermometers. The United States Weather Bureau regards the sling psychrometer as the most reliable instrument for this purpose. In special cases rotary fans or other means may be employed to move the air rapidly over stationary thermometer bulbs.

The *sling psychrometer* consists of a pair of thermometers provided with a handle, which permits them to be whirled rapidly (see Fig. 91). The bulb of the lower of the two thermometers is covered with thin muslin, which is wet at the time an observation is made. This muslin covering should be kept in good condition and should be frequently renewed. It is also desirable to use pure water. The so-called wet bulb is thoroughly saturated by dipping it into distilled water. The thermometers are then whirled rapidly for 15 or 20 seconds, stopped, and quickly read, the wet bulb first. This reading is kept in mind, the psychrometers immediately whirled again and a second reading taken. This is repeated three or four times or more, if necessary, until at least two successive readings of the wet bulb are found to agree very closely, thereby showing that it has reached its lowest temperature. A minute or more is generally required to secure a correct reading. The psychrometer should not be whirled in the direct rays of the sun, and if used out of doors the observer should face the wind. It is a good plan, while whirling the instrument, to step back and forth a few steps further to prevent the presence of the observer's body from giving rise to erroneous observations.

FIG. 91.—SLING PSYCHROMETER.

Fig. 92.

In correcting psychrometric observations the atmospheric pressure at the time must be obtained, and the results deduced from the tables based on a pressure nearest that observed. The difference in the temperature between the wet and the dry bulb is computed to the nearest tenth of a degree. Having the temperature and the pressure of the air and the depression of the wet bulb, it is only necessary to read directly from the tables the dew-point, the vapor pressure, and the relative humidity. These tables will be found in *Bulletin No. 235* of the United States Weather Bureau. A condensed table is given in Fig. 92.

*The Hair Hygrometer.*—This apparatus depends upon the expansion and contraction of a suitably prepared hair under the influence of moisture. It can be made a reasonably accurate instrument, and some types are arranged for continuous record. One of the principal difficulties with hair hygrometers is that a sufficient current of air does not always come in contact with them.

*The Dew-point.*—The dew-point may be obtained by direct observation from Regnault's apparatus, shown in Fig. 93. This instrument consists essentially of a thin polished silver tube *a*, cemented upon the lower end of a long glass tube, as shown. The stopper closing the upper end of the glass tube is fitted with two lateral tubes of hard rubber *b* and *c*, and also carries a delicate thermometer, the bulb of which is placed near the center of the silver tube. The tube *b* extends to the bottom of the silver tube; *c* projects but a short distance through the cork. A rubber aspirating apparatus, as shown, is connected with the tube *b*, and a long tube joined to *c* serves to carry off the fumes. The apparatus is held in a clamp faced with cork or other non-conducting substance.

Observations are made by filling the silver cup with ether or similar volatile liquid, which is caused to evaporate and cool the silver cup by manipulating the aspirating bulb. At the proper point of cooling a deposit of dew is seen to form on the polished silver surface. The object is to ascertain accurately the temperature at which the dew will just deposit. It is necessary that the temperature be lowered very slowly at the critical point, also that there be plenty of liquid in the cup, and

FIG. 93 —DEW-POINT APPARATUS.

that it be agitated sufficiently to have a uniform temperature throughout, and, finally, the surface of the silver must be perfectly clean and in a favorable light, so that the faintest deposit of dew is at once visible. The temperature shown by the thermometer at this moment may be regarded as the temperature of the dew-point. Knowing the dew-point, the humidity of the air may be found by reference to the above-mentioned tables.

**Relation of Humidity and Temperature to Health.**—The physiological significance of moisture in the air varies with many factors, but especially with temperature. In a general way it may be said that moist air is depressing and enervating, while dry air is tonic and stimulating; also that cold air is tonic, while warm air is depressing. Metabolism is slowed in warm<sup>11</sup> air, quickened in cold air. The human body can adapt itself to wide variations in heat and humidity, and by means of suitable clothing and food the range may be greatly increased. Certain combinations of heat and humidity are trying or even hurtful; the most mischievous combinations are *cold damp* air and *warm moist* air, also an excessively dry air, especially when artificially warmed. Many climates in which people are reasonably healthy have a relatively high humidity, and some regions famed for their salubrity are notoriously dry and arid. The frequently changing temperatures and variable amounts of water vapor of most climates are beneficial in stimulating the heat-regulating mechanism.

The vasomotor mechanism and the nervous control of perspiration are stimulated and made vigorous and efficient through moderate cool moving air, especially through changes in the temperature and motion of the air; through well-adapted clothing; cold baths within the limits of reaction; assisted by exercise, normal rest, proper diet, and other factors in personal hygiene that favor good nervous control.

The temperature and humidity of the air affect health mainly by influencing the heat-regulating mechanism of the body. More heat is produced within the body than is required, hence heat must be lost, else heat stagnation or heat stroke will result. The temperature of the air, but still more its humidity, influences heat loss. A stay of about three hours in an atmosphere at 40.4° C. (104.7° F.) and 95 per cent. relative humidity may produce a rise of several degrees in the body temperature of an adult man. It will, therefore, be necessary briefly to review the mechanism by which the constant temperature of the body is maintained.

Excessive moisture makes hot air feel hotter and cold air colder—the first by hindering evaporation and the second by favoring conduction.

The chief source of the body heat comes from the food we eat.<sup>12</sup> Ap-

<sup>11</sup> Metabolism is quickened as soon as the air becomes warm enough to raise the body temperature, but at this point symptoms supervene.

<sup>12</sup> An increase of heat production in a normal individual is due to the taking of food, the doing of muscular work, and the exposure to cold. Fever, acidosis, and certain disturbances in internal secretions may also cause a rise.

proximately 80 per cent. of the food we eat is used to furnish heat to maintain the body temperature, while only about 20 per cent. furnishes energy in the form of motion. Heat is lost from the body chiefly in two ways: (1) by *heat transfer*, or loss by radiation, conduction, and convection; controlled almost entirely by changes in the dilatation and contraction of the blood vessels of the skin; (2) by *evaporation*, chiefly by the evaporation of the water of perspiration; controlled by the varying activity of the sweat glands. Pettenkofer and Voit estimated the loss of water by the lungs at 286 grams, and from the skin at from 500 to 1,700 grams daily. This will give some idea of the magnitude of the effects here concerned. The loss by heat transfer diminishes as the temperature of the surrounding air rises. The temperature of the body would rise when the atmospheric temperature goes above 70° F. were not perspiration then secreted. So long as the perspiration can evaporate freely the heat production and heat loss are balanced. With a high humidity evaporation is lessened and the balance is maintained by rushing blood to the skin, which causes an elevation of the temperature of the surface, and thus the loss of heat by radiation, conduction, and convection is facilitated.

Humidity influences the output of heat from the body in two ways: (1) it increases the conductivity of atmosphere for heat—a cooling influence—hence cold moist air is chilling; (2) it interferes with evaporation of perspiration—a heating influence—hence warm moist air is enervating. There is a neutral zone, around 68° F., at which humidity has comparatively little effect. Hence, if the temperature of a room is kept just right and the occupants are sitting still, it makes little difference whether the air is humid or dry. However, a difference of a few degrees above or below this temperature will have a marked influence.

The so-called "comfort zone" has a maximum temperature, 70° F., a minimum humidity, 30 per cent.; a minimum temperature, 55° to 60° F., and a maximum humidity, 55 per cent. This is the range which most people in temperate climates find agreeable. However, large numbers of people remain comfortable and well in climates that would be trying if the change were made suddenly. The body possesses great powers of adaptability in this regard, which is one of the factors in acclimatization.

Rubner and his coworkers showed that the evaporation of water from the body cannot be regarded as being dependent merely on the percentage humidity of the atmosphere. The temperature of the layer of air in contact with the body is the factor of great importance. Thin clothes and still air, under certain conditions of external temperature, may favor evaporation, while nakedness and moving air favor conduction and radiation. The heat-losing mechanisms of the body are adjustable

to varying conditions within wide limitations, so that diminished loss by evaporation is compensated for by increased loss by conduction and radiation.

According to Haldane,<sup>13</sup> soldiers marching in uniform are liable to heat stroke at wet-bulb temperatures of under 21° C.; that, at 26.7° wet bulb a marked rise of body temperature is noted with muscular exercise, and hard and continuous work is impracticable even when the subject is stripped to the waist; while at 31°-32° wet bulb "in fairly still air the body temperature begins to rise, even in the case of persons stripped to the waist and doing no work; and when once started this rise continues until symptoms of heat stroke arise, unless the person leaves the warm air."

The extensive investigations of the New York State Commission on Ventilation have thrown some new light upon the general problem. These experiments dealt with the effect upon a large number of subjects of three atmospheric conditions: 20° C. with 50 per cent. relative humidity (13° wet bulb); 24° C. with 50 per cent. relative humidity (16° wet bulb); and 30° C. with 80 per cent. relative humidity (27° wet bulb). At 24° wet bulb the average rectal body temperature of the subjects was 2 per cent. higher and at 30° it was 5 per cent. higher than at 20°, showing that the homiothermy of the human body is after all relative and not absolute, even within a moderate range of atmospheric temperature. A somewhat surprising observation was the close relation between the rectal body temperature at 9 A. M. and the mean air temperature for the twelve hours preceding. The curves were so perfectly parallel as to leave no reasonable doubt of the direct relation of cause and effect. There have been conflicting results reported by various observers who have compared body temperatures in the tropics and in the temperate zone; and it may be that after a prolonged sojourn in a warm climate a compensating mechanism is developed which maintains a lower body temperature with a given atmosphere outside.

The New York State Commission on Ventilation found that in addition to a direct effect upon body temperature, atmospheric heat exerts a profound influence upon the general status of the vasomotor machinery as determined by the Crampton value. The Crampton value is an arbitrary index of the general tone of the vasomotor system, obtained from the relation between the changes in blood pressure and heart rate on passing from a reclining to a standing posture.

The amount of moisture in the air conducive to health and well-being is often stated to be somewhere between 50 and 75 per cent. relative humidity. These figures may be very misleading. There is no such thing as a normal humidity, for the amount of moisture in

<sup>13</sup> Eng. Dept. Com. on Humidity and Ven. in Cotton Weaving Sheds, 1910-1911.

relation to health depends upon the temperature, clothing, motion of the air; also upon diet and muscular activity and other factors. Neither the relative humidity nor the absolute humidity nor the temperature of the air alone is a satisfactory guide as to its condition in relation to health. One factor alone gives the sanitarian scant information; however, the temperature as registered upon the wet-bulb thermometer is most significant.

*Importance of the Wet-bulb Temperature.*—The individual susceptibility to temperatures depends entirely on the temperature recorded by the wet-bulb thermometer,<sup>14</sup> no matter what the dry bulb registers. Hill, Rubner, Pembrey, Boycott, Cadman, Nagel, and practically all authorities agree with Haldane that the air of workrooms should not exceed 70° F. by the wet-bulb thermometer. Haldane places the maximum comfort for men at 68° wet bulb, while actual symptoms occur at 78° wet bulb.

Leonard Hill<sup>15</sup> used the Kata-thermometer, which consists of special wet- and dry-bulb alcoholic thermometers, and importance is laid upon the time required to cool the wet-bulb thermometer from 100° to 95° F. In this way, the cooling power of the air may be determined and expressed as a factor.

### THE KATA-THERMOMETER

Dr. W. Heberden<sup>16</sup> nearly 100 years ago pointed out that the actual temperature of the air is only one factor in determining the effect of atmospheric conditions upon the temperature of the body. The humidity of the air, and particularly the movement of the air influence heat loss and body temperature. The cooling power of the air depends upon the temperature, humidity, and movement, and the Kata-thermometer is a measure of these three factors. Studies made with this instrument show that a temperature of 26° C. outdoors, with a moderate breeze blowing, may be more cooling in its effects and hence more comfortable than a temperature of 22° C. indoors with still air. For the same reason, an overheated room with still air in winter is much more uncomfortable than a hotter day outdoors with moving air in summer.

The Kata-thermometer outfit as first proposed by Hill consisted of two specially constructed thermometers with large bulbs and stems graduated from 86° to 110° F., one to be used as a dry and the other

<sup>14</sup>One of the thermometers of a psychrometer is known as the wet bulb. See page 901.

<sup>15</sup>The science of ventilation and the open air treatment. Special Report Series No. 32. National Health Insurance, Medical Research Com., H. M. Stationery Office, 1919.

<sup>16</sup>"An Account of the Heat of July, 1825; together with Some Remarks upon Sensible Cold." Trans. Roy. Soc., London, 1826, Part II, p. 69.

as a wet bulb thermometer. The bulbs are heated to about  $110^{\circ}$  and then placed in clips which hold them in horizontal position, after drying the bare bulb on a clean cloth and jerking excess moisture off the silk covered one. The time taken to fall from  $100^{\circ}$  to  $90^{\circ}$  F. is then noted, best by the use of a stop-watch.

The rate of fall of both thermometers will obviously be affected by air movement and radiant heat as well as by air temperature, and that of the wet bulb by the humidity of the air as well. Dr. Hill believes that the combined influence of these factors will affect the Kata-thermometers very much as it does the human body, and suggests a 45 to 60 second period for the wet bulb and a 150 to 180 second period for the dry bulb as limits for

comfortable atmospheric conditions. Recent studies<sup>17</sup> have indicated that the lower of the limits set corresponds very closely to the average vote of a number of American observers as to bodily comfort. The lower limits may be shorter with advantage, but should not be exceeded.

Further readings may be taken with the thermometers (1) exposed to, or screened from, a source of radiant heat; (2) exposed to, or screened from, wind or

draught; (3) with a thick knitted finger-stall placed over the bulb to imitate the effect of clothes. When this finger-stall is dampened, its efficiency is greatly diminished. Thus the cooling effect of damp clothes may be demonstrated. The effect of the color and texture of clothes may also be demonstrated. A white finger-stall allows the instrument to cool, when exposed to sunlight, much quicker than a dark finger-stall. The latter absorbs the light rays and converts them into heat rays.

Hill, Griffith and Flack<sup>18</sup> have recently presented a detailed study of the physical problems involved, in which the heat loss from the

<sup>17</sup> Winslow, C. E. A.: "The Kata-Thermometer as a Measure of the Effect of Atmospheric Conditions upon Bodily Comfort." *Science*, N. S., 1916, XLII, 716.

<sup>18</sup> "The Measurement of the Rate of Heat Loss at Body Temperature by Convection, Radiation and Evaporation," *Phil. Trans. Roy. Soc., London, Series B*, 1916, CCVII, 183.

FIG. 94.—THE KATA-THERMOMETER.

Kata-thermometer is calculated in a more exact manner in millicalories per square centimeter per second, and the Siebe Gorman Company are now putting out instruments whose factors as compared with a laboratory standard have been determined. These new bulbs are graduated only from 95° to 100° F. The factor divided by the number of seconds it takes to make this five-degree drop gives the rate of cooling at body temperature in millicalories per square centimeter per second. The wet Kata-thermometer gives the rate of cooling by radiation, convection and evaporation. The dry Kata-thermometer gives the rate of cooling by radiation and convection.

This instrument is a distinct improvement over the earlier patterns in that results from different instruments are now directly comparable.

Professor E. B. Phelps, of the United States Public Health Service, has devised an instrument based on the same principle, which has the great advantage of permitting of continuous records of heat loss. It consists of a wet bulb thermometer heated by an electrical coil and constant current of such a strength that in a saturated atmosphere the thermometer registers 8° higher than an unheated bulb.

Such instruments as these, which give us information as to the actual heat loss from the body surface as a result of the whole complex of atmospheric conditions, promise to be of the greatest service in the ventilation studies of the future (Winslow).

Rubner states that an untrained man can be in comfort in a temperature of 75° F. and 80 per cent. humidity (wet bulb about 70° F.) only when he is quiet. At 73.4° F. and 60 per cent. humidity he found a resting man lost by evaporation 75 grams of water per hour, and at 84 per cent. humidity (wet bulb 70° F.) only 19 grams. These figures show that three-quarters of the heat loss may be maintained by conduction and radiation when the wet bulb reaches 70° F.

Cadman concludes that at:

- |        |           |   |
|--------|-----------|---|
| 72° F. | wet bulb. | Inconvenience is experienced, unless heavy clothing is removed and light clothing worn.   |
| 78°    | " "       | ....Little inconvenience is felt if considerable bare body surface is exposed. Hard work is much facilitated if a perceptible current is passing over the body. |
| 82°    | " "       | ....If clothes be removed, and maximum body surface exposed, work can be done providing current of air is available.  |
| 85°    | " "       | ....Body temperature becomes affected, and only light work is possible.   |

Boycott made the following significant observations upon himself:

"At rest and stripped I found that my body temperature rose rapidly if the wet bulb exceeded 88° or 90° F. with a dry bulb of about 100° F., though no rise occurred with a dry bulb of 110° F. and wet bulb of less than 85° F. I have on many occasions spent periods of about an hour in doing ordinary laboratory work in air with the dry bulb at

95° F. and the wet bulb at about 65° F. without any material discomfort. If, however, the wet bulb rises to 88° or 90° F., one's body temperature begins to go up, even when completely at rest, and one becomes exceedingly uncomfortable and on occasions feels very ill. These sensations can be, to some extent, remedied by local cooling of the skin (e. g., cold water on the head), but the rise of body temperature is progressive and must eventually end in heat-stroke."

A man is much less efficient in a warm moist atmosphere; hence it is an advantage to both employer and employee that work be performed at temperatures below 70° F. by the wet bulb. At the lower temperatures work is done faster, more efficiently, and with less fatigue, discomfort, and injury to health. To work in a warm moist atmosphere increases the temperature, pulse, and loss of moisture out of proportion to the work done. It is the master's pockets which suffer under such conditions, for the workers instinctively avoid the discomfort of overheating themselves through lessened exertion.

The New York State Commission on Ventilation clearly showed the effects of high atmospheric temperatures upon the working power—or more properly upon the actual performance of the working organism. Under a strong stimulus the power to do mental or physical work for a short time is not diminished even at 30° C. with 80 per cent. relative humidity. "It is a matter of common experience that even a highly uncomfortable degree of heat is no hindrance to absorbing intellectual work and no bar to a good game of tennis" (Winslow). The disinclination to do active work at a moderately high atmospheric temperature may be interpreted as a conservative and protective process on the part of nature.

**Effects of Warm Moist Air.**—In a hot moist atmosphere an undue amount of blood is brought to the surface of the body, mental and physical activity is reduced, a feeling of depression is felt, and the resulting rise in temperature of the body influences the entire nervous and circulating systems. There is a disinclination to make a physical or mental effort,—in other words, the effect is enervating. When air above 88° F. becomes saturated evaporation can no longer compensate for decrease in radiation, and the body temperature accordingly rises and heat-stroke may ensue. The injurious effects of the summer heat are practically always the result of combined heat and humidity.

According to Rubner and Lewaschew, when the air is very humid the heat loss by evaporation is very much lessened, and, accordingly, at 80 per cent. humidity and temperature of 24° C. (75.2° F.) becomes after a time insupportable to a man unaccustomed to it, and exposure to it is only possible with complete muscular rest. If, however, the air is very dry a temperature of 24° to 29° C. (75.2° to 84.2° F.) can be usually endured. These temperatures are often exceeded in the

summer time in America. By practice a certain amount of accommodation to the effects of a hot moist climate may be acquired.

There is no known serious injury to health caused by working in a warm moist air, provided that a considerable rise of body temperature is avoided. The effects of heat and moisture may be diminished by light clothing, bare legs and arms, whereby the loss of heat from the skin is increased.

Working in moist, overheated rooms has the further disadvantage of wetting the clothes with perspiration, which causes discomfort, dirt, and untidiness, and liability to chilling the surface on going outdoors.

The effect on efficiency is not diminished power, but loss of desire to work. Winslow found that 37 per cent. more work was done at 68° F. than at 86° F.

A poorly ventilated room in which the air becomes vitiated is usually a warm moist atmosphere, and the ill effects of a vitiated atmosphere are mainly caused by the heat and moisture. One of the most mischievous effects of a warm moist atmosphere is disinclination to mental and physical effort and loss of appetite.

**Effects of Cold Damp Air.**—Cold damp air causes a rapid loss of heat and chilling of the body. When such air is injurious the victim is usually underclad, improperly fed, or has been living an indoor life. In certain cases cold damp must always be injurious, as, for instance, where the vital forces are at a low ebb and where there is restricted capacity for making heat, such as infancy or old age; in cases of kidney disease, where hindrance of evaporation and increased metabolism means extra work for the kidneys; also in cases where there is a tendency to rheumatism or disorders of metabolism. The effects of cold damp air may be neutralized by proper clothing, by muscular activity, and, to a limited extent, by diet.

Just how cold damp air influences health is not well understood. It throws an added load upon the heat-producing mechanism to maintain the body temperature; the strain falls especially upon digestion, and metabolism, and also upon the circulation and the kidneys, and indirectly upon the nervous system. Dr. H. I. Bowditch in 1862 formulated the law of soil moisture, and believed that tuberculosis was more common over moist soils than dry ones. According to our present conception, the relation between dampness or moist soil and tuberculosis is quite indirect; if there is any connection it is due merely to the fact that the combination of cold and dampness depresses vitality and thereby lowers resistance.

A person will shiver and the lips turn blue on a very cold misty day, especially when facing the wind. This is due to the fact that under such conditions the respiration is shallow, probably as the result of a

protective mechanism; and the interchange of gases in the lungs is slowed, for moisture interferes with diffusion.

A healthy man may daily move in and breathe cold damp air without suffering in health to any appreciable extent; however, it is generally believed that a cold damp air predisposes to affections of the respiratory passages, to rheumatism, and neuralgias.

**Effects of Warm Dry Air.**—A relatively dry air feels better than moist air at most temperatures. The stimulating and pleasant effects of a dry climate can only be appreciated by one who has visited an arid region—such as our southwestern plateau. However, when air is abnormally dry, especially if warm, the evaporation from the body is greatly increased. Thus, Rubner and Lewaschew found that a man weighing 58 kilograms gave off the following amounts of carbon dioxide and moisture in one hour at different temperatures in dry and moist air:

Temperature	Dry Air			Moist Air		
	Relative Humidity of Air	CO <sub>2</sub>	H <sub>2</sub> O	Relative Humidity of Air	CO <sub>2</sub>	H <sub>2</sub> O
15° C.....	8%	32.2 gm.	36.3 gm.	89%	34.9 gm.	9.0 gm.
20° C.....	5%	30.0 gm.	54.1 gm.	82%	28.3 gm.	15.3 gm.
25° C.....	6%	31.7 gm.	75.4 gm.	81%	31.4 gm.	23.9 gm.
29° C.....	6%	32.4 gm.	103.3 gm.	....	.....	.....

Air that is warm and at the same time abnormally dry, such as that produced by furnace heat,<sup>19</sup> causes an excessive loss of moisture and concentration of the fluids in the tissues and organs of the body. Man consists of 58.5 per cent. of water. A very small percentage of loss may be serious; when the percentage reaches 21 per cent. death results. The warmed and dried atmosphere of our overheated houses gives a sense of chilliness, owing to excessive evaporation, and favors irritation and infection of the respiratory mucous membranes. If a room at 68° F. is not warm enough for a healthy person, we may be sure that it is because the humidity is too low.

The problem of constructing buildings in such a way as to keep the interior up to a fair degree of humidity is a large one. So far engineers have made little practical progress toward its solution. Satisfactory devices may be had to improve the moisture in large public buildings, but these devices have so far proved too expensive for private dwellings, offices, or schoolrooms.

The humidity in living rooms may be improved by setting about growing plants and porous dishes, such as flower pots full of water. If

<sup>19</sup> See page 986.

such receptacles are set near electric fans evaporation is facilitated. Pans or pots of water may also be placed upon the radiator.

A *cool dry air* is bracing. All the body functions are more active, breathing is deeper and more frequent, the circulation of the blood is increased; digestion, assimilation, and metabolism are stimulated.

## CHAPTER III

### MISCELLANEOUS

#### ODORS

People have always believed, and still naturally cling to the notion, that anything that smells bad must be detrimental to health. Science has demonstrated that our sense of smell is a poor sanitary guide. Smell is not primarily a protective sense. Its chief function among animals is to find food and mates. While disagreeable odors may not be harmful, they should be eliminated for esthetic and psychological reasons, as well as for decency and cleanliness.

The viruses of most diseases have no odor whatever. Some diseases, as smallpox, are associated with a disagreeable odor. In no case is the odor diagnostic. Infections in water, milk or food cannot be sensed by smell.

Odors in a living room come mostly from human sources. The sources of these odors are: foul breath, decaying teeth, unclean mouths, nasal catarrh, sudoriferous glands, especially those of the pubes, feet, and axillae, also gases from the stomach and bowels. The decomposition of matter on the skin and also in the clothes adds a very disagreeable odor, accentuated in a warm moist atmosphere. The peculiar odor in some rooms, especially sick rooms, seems to be none of these; just what constitutes the somewhat characteristic man-smell is not known.

While odors may be very unpleasant, they are not known seriously to influence health; contrary to common opinion, they are not by any means a reliable sign of danger. The presence of bacteria or dust in the atmosphere has no special relation to odors. Some poisonous gases, such as carbon monoxid, are practically inodorous.

The air of inhabited rooms ordinarily must be quite full of various scents which we do not appreciate, either because our sense of smell is not keen enough, or because we have become so accustomed to them that they are not noticed. An atmosphere that does not appear to be unpleasant while remaining in a room may seem intolerable upon returning to it after a period in the fresh outdoor air. Man's sense of smell is not keen when compared to that of some of the lower animals; nevertheless it is extremely sensitive to certain odors. Thus, it can

determine 0.000,000,5 milligram of tincture of musk. The acuteness of the sense of smell varies markedly in different individuals.

Odorous molecules detach themselves from the surface of solids and liquids by simple evaporation, by oxidation and by hydrolytic decomposition. Currents of air will carry odors as they carry dust along with them to quite a distance. All odorous substances are freely soluble in oil.

It is well-known that we can perceive odors much more readily when the air is moist than when it is dry. It is also known that the mucous membrane of the nose must be moist in order that an odor be perceived. Most fishes have a well-developed sense of smell.

Passy determined the least amounts of odorous matter that can be perceived by us. He gives the following figures per liter of air in which certain substances are dissolved and can be perceived.

Camphor .....	0.005	milligram	per	liter	of	air
Ether .....	0.004 to 0.005	"	"	"	"	"
Sulphureted hydrogen.....	0.0005	"	"	"	"	"
Mercaptan .....	0.000,000,04	"	"	"	"	"

The olfactory nerves soon tire of most odors, and after a certain time, fail to respond. While in this condition they can at once perceive the sudden appearance of other odors. For example: Aronson found that persons having become insensible to the odor of iodine from continuous use found their perception to the odor of ether at once perfect. Ordinary ventilation does not remove the vapors which are held on solid surfaces by absorption. A jet of compressed air frequently played against the interior surfaces of buildings and against the clothing will remove this source of odors. Hence, the value of opening windows and thoroughly flushing out rooms from time to time.

When a room smells stuffy and close it may be taken as a fairly reliable index that the air is vitiated; this is especially true in a clean room not complicated with odors from clothing and sources other than man. In fact, the odors observed upon entering a room from the outside fresh air often furnish better evidence of imperfect ventilation or lack of cleanliness than laboratory tests.

De Chaumont made accurate observations and found that when the  $\text{CO}_2$  amounts to 6 parts per 10,000 in an inhabited room, the atmosphere begins to smell close and stuffy. Pettenkoffer found air containing 7.5 parts of  $\text{CO}_2$  per 10,000 from the expired breath to have a marked odor, and 10 parts a very unpleasant odor. With a little practice various grades of vitiated air can be detected up to 10 or 12 parts of  $\text{CO}_2$  per 10,000.

The odors from marshes and from decomposing organic matter are not apparently hurtful. One of the most famous stench that has

been recorded, if not the most famous, was that which arose in 1858 and 1859 from the Thames, which at that time was grossly polluted with the sewage of London (Sedgwick). Dr. Budd insisted that no very serious results followed. After giving his proof Budd<sup>1</sup> states: "Before these inexorable figures the illusion of half a century vanished in a moment." We now know that odors in the air bear no reference to contagion or infection and, however unpleasant, need not be feared as such. Sewer "gas" is discussed on page 949.

Winslow and Palmer<sup>2</sup> found that "odors" (?) of vitiated air have an unfavorable influence upon appetite.

The effect of odors upon health is not well understood. When we sense a pleasant smell we involuntarily take deeper breaths; on the other hand, unpleasant odors diminish the respiratory exchange. The latter are accordingly harmful to that extent and the former stimulating. Odors influence the nervous system in various ways; some stimulate, others depress psychic activity; some odors have a well-known influence upon sexuality. Occasionally odors are so disagreeable that they induce nausea, even vomiting. It is remarkable how quickly we may become accustomed to odors, but because our sense of smell has been dulled is no guarantee that the cause of the odors may not continue to produce its effects. Leonard Hill thinks that it is very doubtful if the unpleasant smelling exhalations of the bodies of men have any ill effects on men accustomed to them, and not of esthetic temperament.

Odors in a confined space may be largely removed by washing the air through a spray of water. The water absorbs the odors so that the wash-water smells like a stuffy room. The odors may also be neutralized or concealed with ozone, formaldehyd, and other substances, but the best deodorants are cleanliness and ventilation.

### **LIGHT—OCULAR HYGIENE**

All the rays of the sun pass through the atmosphere before they reach the earth.<sup>3</sup> The air acts as a differential filter, holding back many rays, especially those of shorter wave length; that is, the ultra-violet end of the spectrum. These rays have marked chemical and photodynamic action. We have already seen that some of the heat rays are

<sup>1</sup> Dr. William Budd: "Typhoid Fever: Its Nature, Mode of Spreading, and Prevention," pp. 148-151. London, 1873. This is a remarkable contribution which the student is advised to read.

<sup>2</sup> Proceed. Soc. Exp. Biol. and Med., 1915; XII, 141.

<sup>3</sup> The waves of light are not waves of the atmosphere, but of the ether; however, they are absorbed, reflected or refracted by the dust and moisture contained in the air. It is convenient to consider light, as well as electricity and radio-activity, at this point.

also absorbed by the atmosphere. "More heat and we might be roasted, more light and we might be blinded, more chemical energy and we might be slain like the microbes."

The air as a filter of the sun's rays bears a very important but little understood relation to life. It is now well known that some of the sun's rays have intense chemical and "vital" power. We know something about the chemical rays, the luminous rays, and the calorific rays, but there are doubtless vibrations of which we know nothing. Macfie speculates that, "even, indeed, as the crops of the northern zone outstrip the crops in the south of France, so at certain times may the activity of nations be stimulated or depressed by atmospheric variations affecting the composition of solar radiation."

Light prevents the growth of bacteria and fungi and retards other living processes which ordinarily occur in the dark, such as the development of seeds and the roots of plants. On the other hand, light promotes the development of algae and the higher forms of plants and animals.

Life on the earth depends upon the radiant energy from the sun. Heat, sunshine, and other forms of light, such as X-rays, are physically of the same general nature, and differ from each other only in the degree of intensity of their action. *Light induces or hastens most chemical reactions just as heat does.* The debilitating effect of tropical climates may not be entirely due to the heat, but in large part to the actinic rays of the sun's spectrum.

The physiologic action of light is just beginning to receive the serious attention it deserves. We are all familiar with the calming effect of the dim religious light of churches and the stimulating effect of the glare of the "Great White Way." The intense light of the tropics and of high altitudes is believed in some way to bring on nervous disorders, but the relation is but vaguely understood. Some of the ill effects attributed to bad air and poor ventilation are due in part to the overstimulations of excessive illumination.<sup>4</sup>

*Sunlight* has an important bearing upon health which is highly beneficial. Excessive exposures to sunlight may be harmful, especially in the tropics; on the other hand, we have snow blindness in the arctic zone, and sunburn in any climate. The radiant energy of the sun in outdoor life has a most important influence on the surface temperature of the skin and our feeling of comfort.

Aschenheim<sup>5</sup> found that after an hour's exposure of the body to the direct action of sunlight there was a general leukocytosis in the peripheral blood with a relative increase in the lymphocytes and a decrease

<sup>4</sup>An illuminating discussion of the physiologic action of light will be found in W. M. Bayliss' "Principles of General Physiology," London, 1915, a book which should be studied by all students.

<sup>5</sup>Aschenheim, E.: "Effect of the Sun's Rays on the Leucocyte Count," *Zeitschr. f. Kinderheilkunde*, Berlin, IX, 2.

in polymorphonuclear leukocytes in 80 per cent. of the cases. Lymphocytes are regarded as one of the body's defenses against tuberculosis, and Aschenheim suggests that this may account for the favorable effect of sunlight on tuberculosis. Prolonged exposure of the body to bright sunlight in those who have not been accustomed to its rays may be deleterious and even dangerous. The damage is more than the sunburn resulting, for it may even lead to serous meningitis.<sup>6</sup>

In northern climates, heliotherapy has received considerable attention, and its value has been somewhat exaggerated, whereas in America this form of treatment has been largely neglected.

In 1898, Raab<sup>7</sup> discovered that the effect of sunlight may be greatly reënforced by the action of many fluorescent dyes. Thus, a culture of paramecia was uninjured by acridin (1 to 20,000) in the dark, but in direct sunlight death occurred in six minutes. In the absence of acridin, sunlight exerted but little detrimental influence. All bacteriologists know the germicidal power of sunlight on bacteria, which is due to the rays of short wave length beyond the violet end of the spectrum.

Sellards<sup>8</sup> states that direct sunlight of the tropics (Colombia) exerts no deleterious effect on cultures of malarial parasites, but is moderately deleterious to cultures of *Entamoeba histolytica*. Bilirubin was found to exert a pronounced effect upon the clotting of blood in vitro in the presence of sunlight. A small amount of bilirubin in oxalated plasma exposed to sunlight completely prevented clotting when serum was added. Controls kept in the dark clotted readily.

Bovie<sup>9</sup> points out that the red color of the blood protects our bodies from the actinic solar rays quite as efficiently as we protect our photographic plates by using a ruby light. The pigments of the skin also serve a protective purpose. Blondes are more susceptible to sunburn than brunettes, who also stand tropical climates better than the former.

**Snow Blindness.**—The dazzling reflection of the rays from snow and ice fields is often a source of great annoyance and even danger to mountaineers and arctic explorers. The damage is due to the excess of ultraviolet rays rather than to the intensity and direction of the light. The excessive amount of ultraviolet rays burns the conjunctiva and even the cornea, and may cause serious inflammation. The same effects occur in electric welding. The best protection is afforded by mussel-shaped smoked or tinted glasses in a common spectacle frame.

**Ultraviolet Light.**—The greater number of the constituents of living cells are colorless, that is, they do not absorb rays of the wave length of visible light. Many of them, however, absorb ultraviolet light so

<sup>6</sup>Römer: *Deutsch. med. Wchnschr.*, July 8, 1915, p. 832.

<sup>7</sup>*Ztschr. f. Biol.*, 1900, XXXIX, 524. *Ibid.*, 1903, XLIV, 16.

<sup>8</sup>*Journ. Med. Res.*, Vol. XXXVIII, 3, July, 1918.

<sup>9</sup>*Ibid.*

that radiation of this kind has a powerful effect on living cells. The effects of radium and X-rays on living tissue are similar to those of intense ultraviolet light.

Ultraviolet light and other rays of short wave lengths have chemical and photodynamic powers which must have an important relation to health. They are the most potent and probably the most important rays from the sun and other sources of light. These rays act upon photographic negatives; hasten the hatching of flies' eggs and frogs' eggs; they sunburn the skin and produce freckles; they kill many bacteria, including the tubercle bacilli; they cause heliotropism; they combine chlorin and hydrogen into hydrochloric acid; they cause the oxidation of oxalic acid and other chemical reactions; they blacken silver salts.

It has long been known that various small animals such as tiny crustacea found in fresh water, flee from places "illuminated" by ultraviolet light. The effect of ultraviolet rays is independent of temperature, showing that the reaction is photochemical.

The bactericidal action of sunlight is due entirely to the ultraviolet rays. These rays of short wave length are further considered throughout this section, and also on pages 918, 1144 and 1375.

**Photodynamic Action.**—Familiar examples of photodynamic reactions are the chlorophyll system, retinal processes, and the action of ultraviolet light; also photographic methods and wireless telegraphy. The phenomenon is also considered under the term photochemical reaction, sometimes photosensitization.

Sunlight in the presence of certain fluorescent substances<sup>10</sup> may become surprisingly active, approaching in its deleterious effects on living cells, the order of magnitude of the effects of X-rays and similar short radiations.

The most important of all photochemical reactions is that by means of which the chlorophyll of green plants stores up light energy, and in the process gives oxygen to the atmosphere in return for carbon dioxide absorbed. Chlorophyll absorbs chiefly the red end of the spectrum and therefore is most active during the day.

The combined action of light and certain fluorescent substances may cause skin rashes and serious disorders terminating in death. Thus, buckwheat when fed to sheep and swine for the most part produces no untoward effect, especially in the dark days of winter, when the animals are kept under cover in stalls. But if the animals are white, or have white spots exposed to bright light, then serious symptoms frequently develop (fagopyrismus). The symptoms, if not too far advanced, subside when the animals are returned to darkened buildings, or even if

<sup>10</sup> Phosphorescence and fluorescence represent photochemical reactions with storage of light energy. H. v. Tappeiner und A. Jodlbauer: Die sensibilisierende Wirkung fluoreszierender Substanzen. Leipzig, 1907.

the hair is artificially colored. Under the same conditions of light and food, animals that are dark in color remain well.

Raab<sup>11</sup> was the first to demonstrate that toxic effects can be obtained in small animals, white in color, by eosin, chlorophyll and by the derivatives of hemoglobin. Hausmann<sup>12</sup> injected white mice with hematoporphyrin. Those animals which were kept in the dark developed no symptoms, while those exposed to direct sunlight developed lesions resembling sunburn at the most exposed parts, such as the tips of the ears, nose and tail. Death subsequently resulted. Exposure to bright diffused light produced marked symptoms.

The eruptions on the exposed surfaces in pellagra and other diseases have been explained upon the principles of photosensitization.

The action of light in the presence of fluorescing substances upon red blood corpuscles and immune bodies has been studied by Sellards, Bovie and Brooks.<sup>13</sup> The agglutinating action of ricin, the hemolytic action of croton, the poisonous action of diphtheria and tetanus toxin, and the protective effects of tetanus antitoxin are injured or destroyed by photodynamic action. Many enzymes are susceptible to light alone, but this effect is usually increased by the presence of a fluorescent body.

**Lighting.**—Better lighting, especially daylight, improves health and comfort, makes work and play more agreeable, increases production, and diminishes the chances of accidents. There is no light equal to daylight. The general rule is to have at least one square foot of window to every five square feet of floor space. This will vary with the location, size, shape and purpose of the room. In tropical countries buildings have large wall spaces and small window openings, while in high latitudes the converse has been found desirable. The importance and economy of plenty of daylight has caused a fundamental change in the architectural design of buildings through the invention of the steel sash. Prismatic glass is useful in giving rooms more natural light. Skylights are practical and should be used more than they are. Sharp contrasts must be avoided. A light viewed against the bright sky in day time is scarcely noticed, whereas the same light against a black background is unbearable. Glare from any source is to be avoided. A well illumined room will have both direct and indirect lighting. Direct light gives sharply defined shadows; diffused light gives indefinite and soft shadows, or none at all. The light should be of such a character as to relieve the background of gloom. The light must shine on the object of interest and not in the eyes of the observer. All shades, globes, reflectors, etc., should have this simple object constantly in view. The best direction of light for close work is from the rear, over the left shoulder. A safe

<sup>11</sup> *Zeitschr. f. Biol.*, 1900, XXXIX, 524. *Ibid.*, 1903, XLIV, 16.

<sup>12</sup> *Wien. klin. Wochenschrft.*, 1910, XXIII, 963, 1820.

<sup>13</sup> This article also contains a good discussion and bibliography of the subject. *Journ. Med. Research*, XXXVIII, 3, July, 1918.

rule is that there should be enough diffused light from illumined walls and ceiling so that all parts of the room can be clearly seen. To this add directed light at the points of interest—the work table, piano, or book page.

Good artificial lighting is not a question of the kind of illumination, but of how the illuminant is used. Oil, gas, and electricity produce satisfactory lighting, but each can be abused. Neither ordinary daylight nor ordinary sources of artificial light contain radiations which are injurious to the healthy eye. Electric lighting is clean and does not vitiate the air, and is therefore hygienically superior to gas or oil.

Proper lighting has a direct bearing on the economic running of a factory,<sup>14</sup> and also on the efficiency of the men and the safety of the workpeople. The light must be directed onto the work in such a way that the greatest intensity will be where it is wanted. Under no conditions must the source of the light fall directly in the eyes nor should there be any surfaces which will reflect a strong light into the eyes of the workmen. Flickering lights should always be avoided. Good illumination can only be prescribed where the uses to which the light is to be put are known. See also pages 1335–1342.

**Method for Measuring Illumination.**—The amount of illumination is measured by candle meters or candle feet; that is, the illumination afforded by a standard candle at a distance of one meter or one foot. Shaw<sup>15</sup> believes that the illumination should provide at least 50 candle meters in the most unfavorable part of the room. The maximum hygienic value for illuminants has been found to be about  $2\frac{1}{2}$  candles for each square inch of illuminated surface.

The method which is recommended as a standard procedure depends on the use of photosensitive paper, such as can be obtained from any dealer in photographic materials. By exposing the sensitized paper through a slot in a cardboard for a sufficient period of time, and noting the number of seconds or minutes consumed to match in depth a standard shade or color, the intensity of light can be determined with accuracy. If a fresh piece of paper is exposed to the direct rays of the sun for three seconds it will assume a shade which can be used as a standard for a given series of tests. The intensity of light at other points may be compared with this by noting the number of seconds required to color a fresh piece of paper from the same lot to the same shade.

This method is inferior to photometers, several patterns of which are in use. It is not sufficient for the purposes of ocular hygiene to know the intensity of the light at any particular point. We must know the color and the amount of light that enters the eye; this amount

<sup>14</sup> Code of Lighting for Factories, Mills and Other Work Places. Welfare Work Series, No. 3, Adv. Com., Com. on Labor. Coun. Nat. Defense, Jan., 1918.

<sup>15</sup> Shaw, E. R.: "School Hygiene." The Macmillan Co., N. Y., 1902.

is governed by the size of the pupil, which in turn is governed by the direction of the light, and many other factors. There is therefore no single method for testing illumination with reference to ocular hygiene.

**Errors of Refraction.**—*Myopia* or *near-sightedness* is an error of refraction in which the eyeball is too long and rays of light coming from a distance are brought to a focus in front of the retina. Myopia of moderate degree is usually not progressive and therefore not a serious condition, but progressive (malignant) myopia is a frequent cause of partial or complete blindness. Myopia commonly develops about the eighth or tenth year, and is usually due to hereditary influence. Prolonged near work of all kinds is believed to favor its development. It is also believed that the full correction of myopia by glasses may check its progress. The eyes may apparently tolerate years of abuse, but by middle life the unfortunates may be forced to be sparing of their use at a time when physical limitations curtail the enjoyment of outdoor life. When there is a tendency towards myopia, parents and those engaged in the education of the young should realize the dangers of excessive reading and the prolonged use of the eyes in all kinds of fine near work.

*Hypermetropia* or *far-sightedness* is a condition in which parallel rays of light are brought to a focus behind the retina. Under such conditions clear vision is possible only when this defect is counteracted by contraction of the ciliary muscle, which shortens the eye focus. This constant and unnatural demand upon the ciliary muscle sooner or later results in fatigue, and may cause reflex symptoms such as headache, nervousness, or hyperemia of the conjunctiva or eyelids. It may also cause strabismus or other muscular errors.

*Astigmatism* is an error of refraction caused by an irregularity in curvature in one of the refracting surfaces, usually the cornea. It may cause great impairment of vision. Children supposed to be "backward" at school often may be greatly improved by correcting astigmatism, or other errors of refraction.

*Presbyopia* is the loss of the power of accommodation due to advancing years, caused by an increasing hardness of the crystalline lens. It usually makes itself manifest between 40 and 50 years, and increases until 55 or 60 years of age.

**Color blindness** was first accurately described in 1774 by Dalton, an English chemist, who himself was color blind. Color blindness may be partial or total, congenital or acquired. To those who are totally color blind, the world appears as though it were tinted with different shades of gray. In normal color perception, six colors are seen in the spectrum: red, orange, yellow, green, blue, and violet. Even in normal cases, with a diminution in the intensity of light, the orange, blue and yellow may be missed. Those who see only three colors—red, green

and violet—are markedly color blind; those who see only two colors—yellow and blue—are especially dangerous, because they cannot distinguish red from green.

Total color blindness is rare, but congenital partial color defect is common, occurring in about 4 per cent. of all males, but only in about 0.2 per cent. of females. The percentage is higher among Quakers. Color blindness of a degree dangerous in occupations requiring recognition of colored signal lights, occurs in about 3.1 per cent. of men and in about 0.7 per cent. of women. In total color blindness, consanguinity in the parents has been traced in 12.5 per cent. of the cases. The condition is usually inherited (page 650). The most common cause of acquired color blindness is the immoderate use of tobacco and alcohol (page 94).

The occupations in which the color sense is important are: All naval and marine officers, pilots and certain classes of seamen, locomotive engineers, and all occupations in the arts requiring mixing pigments or matching colors.

The Holmgren test consists in matching various colors from a confused mass of skeins of colored yarns. The three chief test colors are pale green, light pink and bright red. The Jennings self-recording worsted test is an improved modification of this skein test, but results in the rejection of a large percentage of subjects who should be accepted for sailors or trainmen, and it therefore should be supplemented with the Eldridge-Green, or the Williams lantern test.<sup>16</sup>

**Eye Strain.**—Any decided derangement in the build of the eyes or in the proper balance of the ocular muscles may exert a profound influence upon the general system. It is rare that these reflex symptoms arise in other than workers who employ many hours daily in close use of the eyes. The most common symptom caused by eye strain is headache. The eyes themselves may present nothing abnormal in the way of congestion. Other symptoms are print blurring, restricted distant vision, occasional double vision, in fine, those symptoms usually described under the term asthenopia. There may be digestive disturbances, vertigo, car sickness, choreic twitchings, faulty positions and spasmodic movements of the head, and a great variety of other manifestations. The prevention of eye strain requires proper correction of refraction, care to secure the right kind of illumination, and in some cases by systematical resting of the eyes.

**Care of the Eyes.**—Short periods of rest should interrupt all kinds of close work, during which the eyes should be directed on distant objects. This relaxes the muscles of accommodation. Reading in a recumbent posture should be avoided, and reading should never be persisted in when drowsy or physically tired. Books printed in very small

<sup>16</sup>Collins, G. L.: "Color Blindness." *U. S. P. H. Bull.* No. 93, 1918.

type or on poor paper should be avoided (page 1343). Automobiling and moving pictures are somewhat harmful to the eyes.

If the eyes feel hot and uncomfortable after exposure to irritants or undue strain, they may be washed with a saturated solution of boric acid. Bathing the closed lids with either very warm or cold water is refreshing and beneficial.

After measles and other fevers the softening and congestion of the ocular tissues requires a long period during which the eyes should be used but little at close work. The health of the eyes is dependent in large measure upon the health of the body.

Children should be taught as early as possible never to gaze long upon any near object brightly illuminated. Note must be taken of the harmful practice of riding babies in coaches with the full glare of the sun directly upon their faces. Children should be protected from all toys and articles with sharp edges or points which can injure the eyes. Workpeople also require protection against flying particles (page 94). When twilight supervenes, artificial lights should go on, unless the parent wisely utilizes this witching hour with amusement or instruction that rests the eyes.

For the purposes of ocular hygiene the direction, source, power and color of artificial illumination are all important. The amount of illumination should not be judged by the brightness of the lamps, but by the amount of light at the place it is needed. This varies; thus more light is needed for sewing on black cloth than on white cloth. The light should be steady. A flickering light tires the muscles that govern accommodation and leads to fatigue and pain. Reading in railway trains causes similar strain: the eye muscles tire of trying to follow the shaking page. It is contrary to the principles of ocular hygiene to face a glaring light, especially when reading, writing, or any other work requiring close application. Even though the light may come from above, glaring reflections from polished metal or brass, from brightly varnished surfaces, or even from glossy white paper may be very trying because a bright light from below falls on the part of the retina which commonly gets light only from grass or dark surfaces. For the same reason glare from snow and sand is not only disagreeable on account of its intensity, but because of the unusual direction from which it comes.

Vision should be tested by competent persons at regular intervals—frequently, during the period of growth and again at the presbyopic age, 40 to 60 years. See also pages 1334 and 1342.

The eyes are a more frequent portal of entry to infections than we have suspected. The conjunctivae communicate, through the lachrymal ducts with the nose, and there is a constant flow of tear secretion in this direction. Microorganisms introduced into the conjunctival sac

may be isolated from the nose in five minutes, from the throat in fifteen minutes, and from the stool in twenty-four hours.<sup>17</sup> Thus, diphtheria, common colds, influenza, pneumonia, and other respiratory infections and even intestinal diseases may be contracted. Face masks that do not protect the eyes are therefore inadequate.<sup>18</sup>

## ELECTRICITY

The question of electricity is also a question of vibrations, not of the air, but of ether, and one shrouded in much obscurity. The electric potential of the air varies considerably. It is highest in winter and lowest in summer, and shows diurnal variations. It is increased by winds and is especially increased by the condensation of vapor. It also increases as we ascend.

It is assumed that electric changes in the air and in other objects surrounding us exercise an influence on health and vitality, but the influence is obscure and mainly a matter of conjecture.

## RADIO-ACTIVITY

Soon after the discovery of radium by the Curies it was proved, chiefly through the investigations of Elster and Geitel, that the air and soil and certain mineral springs contained radio-active substances. Newly fallen rain and snow are also radio-active. Air drawn from the soil by means of a pipe, or air shut up in underground cellars and caverns, is especially radio-active, as is also the air on mountain tops. The air in clear weather has greater radio-activity than in dull weather.

Certainly radio-active substances have important physiological, physical, and chemical effects. They ionize the air, rendering it a conductor of electricity; they cause a fluorescence of certain chemical substances; they produce a sensation of light if they strike the eye; applied to the body in sufficient "dosage," radium,  $\alpha$ ,  $\beta$ ,  $\gamma$  and X-rays cause destruction of tissue, changes in the blood, and general constitutional symptoms. Local destruction of tissue is not specific, except perhaps for lymphoid structures, as in Hodgkin's disease. See Ultraviolet Rays, page 918.

## SMOKE

Smoke is a product of combustion and consists of a mixture of gases containing solid particles.<sup>19</sup> Ordinary smoke consists largely of unburned carbon particles, hydrocarbons, and other pyroligneous products; gases, some of them poisonous, such as carbon monoxid; also mineral acids, etc. Angus Smith give the following analysis of smoke from a common house fire:

*Smoke from a common house fire*

	Carbon Dioxid	Carbon Monoxid	Oxygen	Nitrogen
Gas from chimney 4 feet above the fireplace..... {	0.35 1.65	.... 0.38	16.93 19.29	80.02 78.68
Gas from the middle of a good fire. A great mass of coal over the fire, the gas taken from below the glow- ing mass..... {	19.46 20.90 17.50 17.44	0.09 0.10 .... ....	..... ..... 0.60 0.39	80.45 79.00 80.04 82.17
A heap of glowing coal, gas taken close to spot where carbonic oxid was burning..... {	15.43 18.17	3.49 2.48	0.96 .....	80.12 79.35
Gas from clear fire below..... {	16.10	....	4.95	78.95
Gas from the same fire at upper part, 1 inch below the surface..... {	17.21 18.20	.... 0.99	4.25 .....	78.54 78.21

Dr. Cohen of the Manchester Air Analysis Committee gives the following analysis of soot collected from the roofs of glass houses in Kew and Chelsea:

	Chelsea Per Cent.	Kew Per Cent.
Carbon.....	39.0	42.5
Hydrocarbons.....	12.3	4.8
Organic bases (pyridins, etc.).....	2.0	....
Sulphuric acid.....	4.3	4.0
Hydrochloric acid.....	1.4	0.8
Ammonia.....	1.4	1.1
Metallic iron and magnetic oxid of iron.....	2.6	....
Mineral matter (chiefly silica and ferric oxid).....	31.2	41.5
Water not determined (say difference).....	5.8	5.3

Large manufacturing chimneys are the chief offenders. There are two main causes of smoky chimneys: (1) insufficient boiler capacity, and (2) improper stoking. The cure of the smoke nuisance consists in the installation of boilers of sufficient power so that they need not

<sup>19</sup> Smoke consists largely of solid particles suspended in the air; fog, of liquid particles.

be forced, and the use of mechanical stokers. The electrification of railroads and the more general use of electric power generated from water pressure help materially to lessen the amount of smoke in cities.

The London County Council permits black smoke for five minutes after the lighting of furnaces. Other towns allow as much as 15 minutes. Most laws distinguish between black smoke and white smoke, although the one is about as pernicious as the other.

In Boston the density of the smoke is graded into four classes, in accordance with Ringelmann's chart. This is a rather complicated system, depending upon the character of the stack, the density of the smoke, and the time, as shown in Fig. 95.<sup>20</sup>

The amount of smoke in some manufacturing centers is almost incredible. Dr. W. N. Shaw estimates that London gives to the atmosphere every day about 7,000,000 tons of smoky air containing over 400 tons of soot, and he calculates that smoke deprives London of about one-sixth its possible sunlight and daylight in summer and about one-half its possible sunlight and daylight in winter.

The injurious effect of smoke on health has perhaps been overestimated. It acts directly and indirectly. Directly it irritates the mucous membranes of the upper respiratory passages, and Asher and also Rubner believe that it increases the mortality from acute pulmonary diseases. They state that smoke and soot predispose to acute pulmonary tuberculosis. Indirectly smoke is a source of dirt and general nuisance and leads to depression of the spirits. It shuts out the light, soils with soot, and deters the opening of windows in order to let in fresh air. The presence of mineral acids in the air has a corrosive influence upon inorganic substances, and doubtless acts injuriously upon plant and animal life. The economic losses from the soiling action of soot are enormous. Even if it were not injurious to health, smoke is so evident a nuisance that communities are justified in every effort to check and prevent this growing abomination.

Klotz<sup>21</sup> characterizes pulmonary anthracosis as a community disease. He found as much as 1.2 to 5.3 grams of carbon in the lungs of persons living in Pittsburgh, while only 0.14 and 0.4 gram in the lungs of two residents in Ann Arbor, Mich. Anthracosis then affects city dwellers in proportion to the amount of smoke in the air. The amount of carbon in the lungs is dependent upon the amount inhaled. Carbon in the lungs causes a loss of elasticity of the tissue; structural changes, especially fibrosis, about the anthracotic deposits; the air spaces are encroached upon, resulting in compensatory emphysema. When anthra-

 2. Equivalent to 40 per cent black  
 3. Equivalent to 60 per cent black  
 4. Equivalent to 80 per cent black

INSTRUCTIONS FOR USING THE RINGELMANN CHART.—Hang smoke chart on a level with the eye, about 50 feet from observer, as nearly as possible in line with chimney. Glance from smoke to chart and note corresponding number, recording same and time of observation. Repeat observations at one-fourth or one-half minute intervals. From these records the average density may be determined for each hour or for each day. No smoke is recorded as No. 0. 100 per cent black smoke is recorded as No. 5. Experienced observers often record in half chart numbers.

cosis is well marked it seriously impairs the function of the lungs. Pleural adhesions do not develop as a result of the deposit (page 931).

Smoke polluted with poisonous chemical vapors may be quite serious. Thus, hydrogen sulphid, found in large quantities in the smoke generated in sulphate of ammonia and tar works and from alkali wastes, is a poisonous gas. The arsenical vapors given off chiefly from lead and copper smelters kill vegetation for wide areas around.

## FOG

Fogs are caused by the condensation of water vapor on particles of dust. Dust particles have a varying capacity for condensing and attracting moisture, depending upon their power of radiating heat and on their affinity for water. Carbon dust is hygroscopic and, therefore, encourages fogs. The ammonia and sulphuric acid in smoky air also occasion and aggravate fog. The air of manufacturing cities, therefore, possesses all the elements to form a fine persistent fog which forms a "chemical pall" between the city and the sky.

The more carbon a fog contains the blacker it is. The general result of a fog is to shut out sunlight and fresh air and to "partially suffocate unfortunate citizens in clouds of noxious chemicals." Fog contains all the irritating properties of smoke in a concentrated form, and it also in a measure prevents the escape of the city-made carbon dioxide. The  $\text{CO}_2$  in the city air during a fog may rise to 10 parts per 10,000. If smoke is bad fog is ten times worse. It has been shown that during city fogs sickness increases and the death rate rises. From the economic standpoint fog causes greater financial losses than smoke. Russell calculates the annual loss to the people of London from fog to total about \$9,000,000 a year. The main items in this loss consist in extra washing, including extra soap, the damage to dresses, curtains, carpets, and textile fabrics, the replacing of wall-papers, and the painting of houses, the restoring of gilt and metal work, the slow destruction of granite, marble, and stonework of buildings, the extra cost of artificial illumination, etc. This estimate does not include the losses resulting from its action on health.

## DUST

Dust is not only a nuisance, but under certain conditions is known to be prejudicial to health. Dust is in reality a normal and very important constituent of the air; it exists everywhere in the atmosphere and profoundly affects some of the physical conditions of our environ-

ment. One of the most important functions of dust is to limit the humidity of the air by causing the precipitation of moisture in the form of rain, and to help control temperature by the formation of clouds, mists, and fogs. Aitken, who has made a special study of this subject, says that without dust "every blade of grass and every branch of tree would drip with moisture deposited by the passing air; our dresses would become wet and dripping, and umbrellas useless; but our miseries would not end here. The insides of our houses would become wet; the walls and every object in the room would run with moisture." Without dust there would be no rain, no clouds, no mist, for the water vapor which condenses upon each particle of dust forms the nucleus of a raindrop.

Dust disperses the light and decreases the transparency of the atmosphere, especially if the atmosphere be also humid. What is known as haze is really dust carrying a minute amount of moisture.

Although dust particles are universally present in the known atmosphere, they are very irregularly distributed. Organic dust exists only in the lower strata, while inorganic particles are found wherever the air has been examined. Ordinarily there is more dust indoors than in outdoor air. The size of the dust particles varies enormously, from gross masses to microscopic and ultramicroscopic particles. The vast numbers and universal presence of these particles may be realized by examining a sunbeam. Air free of dust is an artificial product obtained only with special care in small amounts in the laboratory.

Most of the dust is torn from the earth by the winds; much of it comes from the carbon and other particles in smoke; considerable amounts consist of minute grains of salt derived from sea spray; and great quantities are added by volcanoes. Finally, the air contains interplanetary particles which fall through it in a constant shower.

The spectrum shows the bands of sodium everywhere in the atmosphere. This is lifted into the air by the wind from the sea spray. The water evaporates, leaving the salt particles to float about at the will of the wind.

Organic dust consists of the dry and disintegrated particles which are blown into the air from the animal and plant kingdoms. They consist of epithelial scales, seed, spores, bacteria, pollen, plant cells, fluff of various kinds, bits of insects, starch, pus cells, algae, rotifers, fragments of hair, feathers, and bits of tissue, fibers of cotton, etc.

The inorganic dust, which is derived mostly from the soil, from the sea, and from interplanetary space, consists chiefly of silica, aluminium silicate, calcium carbonate, calcium phosphate, magnesia, iron oxid, sodium chlorid, etc.

Modern cities are dust producers. Whipple found the number of dust particles visible with a magnification of 100 diameters, at the air

inlets of some of the commercial buildings in Boston, as determined by microscopical counts, to range from 100,000 to nearly 1,000,000 per cubic foot.

The number of particles vary from one per cubic centimeter on mountain tops on exceptionally clear days to millions per cubic centimeter in ordinary indoor air. Considering only particles of hygienic importance, namely, those having a diameter of 0.0001 square millimeter or over, recent analyses show 900 particles per liter, or 0.11 gram per million liters of country air on a clear day. At the other extreme, 760 grams per liter or 24,000,000 particles per liter, have been found in the air of an abrasive factory.

The number of dust particles in a room is inversely proportioned to the amount of fresh air supplied. Ordinary air washers remove from 20 per cent. to 70 per cent. of the dust.

Dust particles may be carried enormous distances by the winds. Ehrenberg detected organisms belonging to Africa in the air of Berlin; and fragments of infusoria belonging to the plains of America in the air of Portugal. The smoke of the burning of Chicago reached to the Pacific coast. The volcanic dust of Krakatoa, consisting chiefly of glassy pumice, was found for years in our atmosphere, and it is assumed that some of it may have traveled several times around the world. Macfie has seen in the Canary Islands clouds of dust sufficient to obscure the sun, though the dust had come all the way from the African mainland. All of us living on the Atlantic seaboard have seen the yellow days caused by forest fires several thousands of miles away.

**Dust and Disease.**—"Normal" atmospheric dust, free from bacteria, causes no appreciable irritation to the healthy respiratory mucous membranes. Dust becomes injurious when excessive in amount or when irritating in character, or when it contains injurious microorganisms; the injury also depends upon the constancy of its presence and somewhat upon the susceptibility of the individual.

Dust may act indirectly as a predisposing cause of many infections, as well as directly irritating and inflaming the respiratory passages. The statement that dust opens the door to tuberculosis and other infections of the air passages, such as common colds, influenza, pneumonia, etc., can no longer be questioned. We must first limit ourselves to a consideration of the effect of dust free of noxious bacteria; in the next section we will discuss the question of bacteria in the air.

The general effect of mineral dust breathed for a long period of time is to cause an irritation of the mucous membranes and an inflammatory condition of the lung tissue. The term *pneumonokoniosis* is a general name for affections of this kind. The term is modified according to the various kinds of dust. Thus, *anthracosis* is caused by coal dust;

*siderosis* by iron or steel dust; *silicosis* or *chalicosis* by stone dust; *byssinosis* by cotton particles or vegetable fiber dust.

In certain cases the dust is retained as deposits in the lungs and neighboring lymph glands without further damage. The lungs and bronchial glands of all adults are more or less discolored from particles, which are constantly inhaled. The particles are taken up by the phagocytes and deposited in the lymphatic spaces of the lung or carried to the neighboring lymph glands, where they are enmeshed. Under certain circumstances the dust irritates the delicate structures and leads to infections and destruction of tissue. Thus, we hear of stone mason's phthisis, steel grinder's phthisis, and potter's rot. It is not always easy to distinguish between the fibrosis resulting from tuberculosis and pneumonokoniosis, except by repeated sputum examinations, sometimes extending over a number of years.<sup>22</sup> Among the dusty trades may be mentioned pottery and earthenware manufacture, cutlery and file-making, certain departments of glass-making, copper, iron, lead, and steel manufacturing, stone-cutting, chimney-sweeping, textile trades, etc. Oliver ("Disease of Occupation") examined the atmosphere in which the brushers-off, the finishers, and the porcelain-makers generally work, and found it to contain 640 million particles of dust per cubic meter of air, while several of the finishers, i. e., the persons whose work consists in removing the excess of the dried glaze on the ware, are often breathing an atmosphere containing 680 million particles of dust to the cubic meter. It is little wonder that bronchitis and phthisis are common.<sup>23</sup>

Winslow and Kligler<sup>24</sup> report an average of 49,200,000 microbes per gram in New York street dust, and between 3,000,000 and 5,000,000 per gram in indoor dust. Street dust includes the colon bacilli and acid-forming streptococci.

Dust consisting of inorganic particles is more harmful than dust consisting of organic particles, because the former are sharper and more irritating. House dust is more harmful than outside dust, not only because there is more of it, especially in badly ventilated and ill-kept rooms, but because it is more apt to contain living pathogenic bacteria. House dust may be kept down by cleanliness and avoidance of dry dusting and sweeping; by the use of vacuum cleaning; and by free ventilation. Much house dust is blown in from the outside, and some of it comes in on dirty shoes. In buildings ventilated with a mechanical system the air may be filtered through bags or passed through a water curtain, which will eliminate much dust. Oiling floors with a wax or paraffin mixture helps to keep down indoor dust. Carpets tacked down are

<sup>22</sup> *Journal Ind. Hyg.*, July, 1919, 1, No. 3, p. 366.

<sup>23</sup> For a discussion of the dusty trades, see chapter on Industrial Hygiene. Anthracosis is considered on page 927.

<sup>24</sup> *Am. Jour. Public Health*, 1912, II, 663.

sanitary abominations and should be replaced with rugs that permit outdoor cleaning and sunning.

Street dust contains coal dust, metallic dust from the operation of trolley cars, material swept from houses and from shaking rugs from windows, the grinding up of roadbeds by vehicles, ashes, and other materials blown from barrels and teams: the bacteria are derived from dried fecal matter from horses and other animals, dried sputum, the soil, and a variety of other sources. Street dust may contain pathogenic organisms, such as the tubercle bacillus, many varieties of cocci, the colon bacillus, *Bacillus aerogenes capsulatus*, and possibly, under special conditions, tetanus, malignant edema, and occasionally other pathogenic microorganisms. Street dust, therefore, becomes more than a nuisance, for it is not only irritating, but may be a source of infection.

To keep down street dust requires, first of all, a well-constructed road with a good surface, oiled or properly cared for; the control of animals; the covering of ash barrels and carts hauling dusty loads; the use of automobile vacuum cleaners to replace the old or the present-day methods of dry sweeping. Attention must also be given to spitting on sidewalks and streets, the enforcement of smoke ordinances, the more extensive flushing of streets, and general attention to cleanliness.

When dust is violently stirred up by dry sweeping or beating carpets, or still more by a March wind in a dry, dirty street, the quantity inhaled with attached microorganisms has a real sanitary significance.

The pollen of certain plants flying in the air as dust leads to hay fever in susceptible individuals.<sup>25</sup> See Anaphylaxis, page 593.

**Methods for Examining Dust.**—*Impaction Methods.*—The air is forcibly blown against surfaces specially prepared with sticky substances, such as gum acacia, glycerin, silicate of soda or resin, held by porcelain or glass plates, glass tubes or paper. The dust may be allowed to settle upon a Petri dish. Particles are then examined under the microscope or weighed. The well known effect of dust upon a photographic plate can be used to register the number and size of the larger particles.

*Electrostatic Method.*—The electrostatic precipitation of dust

particles depends upon the ionization of finely divided substances in an electric field. This method is based upon the laws of electrically charged bodies, and has recently been applied commercially to the recovery of valuable dusts. Its use for the sanitary analysis of air was studied by Bill.<sup>26</sup>

*Filtration Methods.*—Dust may be collected from the air by passing it through cotton, sugar, extraction thimbles, resorcinol, fine mesh wire, cloth, water, filter paper, collodion, wool, cheese cloth, canton flannel, etc.

FIG. 96.—THE PALMER WATER-SPRAY APPARATUS FOR THE COLLECTION OF AËRIAL DUST.

New York State Commission on Ventilation.

The Palmer Water Spray Apparatus,<sup>27</sup> as worked out by Palmer, Coleman and Ward, is the most generally useful method; it is as follows: In air not visibly very dusty 200 to 400 cubic feet of air should be passed through the washer, while in more dusty air 100 to 200 cubic feet will suffice. About 40 c. c. of distilled water is placed in the trap and about once in five or ten minutes (depending on the temperature and humidity of the atmosphere) water is added to make up the loss from evaporation. After the run is completed the water with its suspended dust is

drained into a bottle, the bulb is rinsed several times with distilled water, and the original water plus the washings are made up to 100 c. c. One c. c. of this suspension after thorough shaking is transferred to a Sedgwick-Rafter cell and five fields, at the center and four corners, counted under a two-thirds inch objective. Where both light and heavy dusts are present this procedure must be repeated for the top and the bottom of the cell. A second c. c. is then placed in the cell and counted in the same way. The dust particles may conveniently be grouped in five classes, according to size, as follows:

1. Large masses about 100 standard units (.04 sq. mm.).
2. About 25 standard units (.01 sq. mm.).
3. About 1 standard unit (.0004 sq. mm.).

<sup>26</sup> *Journ. Ind. Hyg.*, 1, 7, Nov., 1919, p. 323.

<sup>27</sup> *Am. Journ. Public Health*, Jan., 1916, VI, p. 54.

4. About  $\frac{1}{4}$  standard unit (.0001 sq. mm.).

5. Dust too fine to count,—presence indicated by a plus sign.

A control count should always be made using the same slide and the same batch of distilled water; and the average of the five field counts obtained subtracted from the average of the ten field counts of the suspension of dust.

The remainder of the suspension should be filtered through a weighed Gooch crucible, the crucible and contents dried for one hour at approximately 100° C. and weighed to 0.1 mg.

*Condensation Methods.*—Condensation methods depend upon the condensation of water vapor about dust particles in a rarefied atmosphere.

The koniscope, invented by Professor John Aitken, consists of two brass tubes connected at right angles and suitably fitted with stopcocks and a small air pump. By exhausting the air from one of the tubes, allowing the space to become saturated with water vapor by evaporation from wet blotting paper within, and then allowing this moisture to condense upon the dusty atmosphere under examination, clouds of different degrees of density will form inside the tube. The approximate density of the clouds can be measured by looking through the tubes, windows being provided for this purpose. A table is supplied with the instrument to give the approximate number of dust particles corresponding to clouds of different degrees of density. This method has limited usefulness, because it makes apparent exceedingly minute particles that have little sanitary significance.

All the methods for examining dust in the air are faulty in one or more respects; none of them accounts for all the dust.

## CHAPTER IV

### BACTERIA AND POISONOUS GASES IN THE AIR

#### BACTERIA IN THE AIR

The number of bacteria in the air ordinarily has a direct relation to the amount of dust; in fact, many of the bacteria in the air are attached to dust particles. Bacteria in the air are commonly considered as one kind of dust, but on account of their significance they are given separate consideration.

Bacteria are not found everywhere in the air; uninhabited places are quite free; and the number diminishes as we ascend.

Bacteria do not multiply in the air; in fact, most of them soon die, especially when exposed in dry air to sunshine. For the most part, the bacteria in the air belong to the harmless varieties, although the number and kind vary greatly with circumstances. They come chiefly from the soil and are carried into the air by the wind and traffic movements; that is, bacteria in the air are derived from practically the same sources as dust. The dangerous bacteria in the air, however, come directly or indirectly from man and some of the lower animals.

The number of bacteria differs greatly with the local conditions. There are more in the air of towns than in the open country; few in high mountains, desert places, or at sea; more in windy weather than calm air; more indoors than in outside air; more in dry air than in moist air; more before than after rain. The air of badly ventilated rooms, especially if not kept clean, contains very many bacteria, and more when occupied, as the movements of the occupants stir up the dust.

Miquel of the Observatory of Montsouris studied the number of bacteria in the air of various localities. He found about 150 per cubic foot in the air of Paris, but only 6 after rain; on the top of the Pantheon he found  $1\frac{1}{2}$ ; in the streets about 12 per cubic foot; in a neglected hospital 3,170; in a gram of laboratory dust 75,000 and in a gram of house dust 2,100,000.

Flügge considers that on the average there are about one hundred microorganisms to a cubic meter of city air—an average evidently below that of Paris.

Dr. Jean Binot did not find a single bacterium in 100 liters of

outside air taken at the summit of Mont Blanc; and he found a progressive decrease in the number as the height increased. Thus, he found:

At Montanvert .....	49
At the Mer de Glace .....	23
At the Place de l'Aiguille .....	14
At the Grand Malet .....	8
At the Grand Plateau .....	6
On the summit .....	0

Again, Graham Smith found at the top of the Clock Tower of the Houses of Parliament in London only one-third of the number at ground level.

Whipple found 1,330 bacteria per cubic feet in the air, at the street level, while at the tenth story of the John Hancock building in Boston the air contained 330.

Speaking broadly, from two to three hundred times as many particles of dust as bacteria are found in the outside air of cities.

Haldane found 256 bacteria per cubic foot of air in an unventilated room compared to practically none in a ventilated room.

Pasteur, in experiments that will ever remain classic, exposed organic infusions in flasks to the air of various places, and used the results thus obtained to prove the presence or absence of bacteria in the air and to dispel the illusion of spontaneous generation. Of 20 such flasks exposed to the air of the Mer de Glace 19 showed no contamination. About the same time (1875) Tyndall exposed 27 flasks containing an infusion to the air of the Aletsch glacier (8,000 feet); none showed putrefaction, while 90 per cent. of the flasks opened in a hayloft were "smitten."

It is estimated that a person living in London breathes about 300,000 microbes in the inspired air each day. Winslow and Brown<sup>1</sup> examined 1,037 samples of air, both indoors and outdoors, with counts varying from two to 5,200 per cubic foot.

The expired air, during normal respirations, is practically bacteria-free, no matter how many may be contained in the inspired air. The moist mucous membranes of the upper respiratory passages act as a bacterial trap. When the expired air contains bacteria it is only as a result of coughing, sneezing, talking, or other forced expiratory efforts (see Droplet Infection).

The number of bacteria in the air is seldom a factor of sanitary significance, except under special circumstances, such as dairy conditions or studies in droplet infection.

The harmful bacteria in the air and the danger of contracting disease through air-borne infection are considered below.

<sup>1</sup> *Monthly Weather Rev.*, 1914, XLII, 452.

**Method for Determining Bacteria in the Air.**—A rough idea of the bacterial population of the air may be obtained by exposing suitable culture media in Petri plates for various periods of time, and counting the colonies which develop from the germs falling upon them.

FIG. 97.—MAGNUS ASPIRATOR.

A large number of different devices have been described for a more accurate determination of the number of bacteria in the air. These are all adaptations of the three general methods: (1) filtration of air; (2) bubbling air through some liquid medium; (3) precipitating the bacteria from a given volume of air. Each of these methods can be made to give fairly satisfactory results in the hands of competent workers, but the Committee of the American Public Health Association recommend the following method of Petri on account of its simplicity and general applicability:

**Filtration Method of Petri.**—The filter tubes are glass tubes  $1\frac{1}{2}$  cm. in diameter and 10 cm. long. In the end of each is placed a perforated cork stopper, through which a glass tube 6 mm. in diameter is passed. The filtering material consists of sand which has been passed through a 100-mesh sieve. The sand in the filter tube is 1 cm. deep and supported by a layer of bolting cloth covering the cork. Two filter tubes are connected in tandem, and a measured volume of air, 10 liters or more, is drawn through at a constant rate by suction. The suction is applied by means of an aspirator of known volume, preferably one of the double or continuous type. Either the Magnus aspirator (Fig. 97) or the double aspirator (Fig. 98) are suitable for this purpose. Before using a pair of filter tubes a test for possible leakage is made by placing the thumb over the cotton stopper and applying the aspirator; if the suction is weak or absent the corks must be tightened or the tubes discarded. All corks should be tightened and connections wired and the apparatus sterilized before using the filters. The collection of the sample should take from 1 to 2 minutes per liter.

FIG. 98.—DOUBLE ASPIRATOR.

After filtering a definite volume through the tubes the sand is poured into 10 c. c. of sterile water, thoroughly shaken, and aliquot portions plated in ordinary nutrient agar, all plates being made in duplicate. The plates are incubated at room temperature for five days, when final counts are made.

*Rettger's Method.*—An improved method of enumerating air bacteria has been described by Rettger,<sup>2</sup> which commends itself as the best method yet devised. The method consists of bubbling a given quantity of air through salt solution. The bacteria in the air are trapped in the salt solution, which may then be planted in the usual way and the number of colonies counted.

**Air and Infection.**—The air was long regarded as the vehicle and even the source of the communicable diseases. Theories, such as noxious effluvia, poisonous emanations, and infectious miasms, gave way with the advent of bacteriology. When the early classical researches of Pasteur, Tyndall, and others showed that bacteria exist in the air almost everywhere in greater or in lesser numbers, the conclusion was jumped at that the air must be particularly dangerous. Within recent years, however, we have learned that the air is not very much to be feared on account of the bacteria it may carry, except under occasional circumstances. This change in our views during recent times is nowhere better illustrated than in the relation of the air to surgery. During the early days of antiseptic surgery so much fear was entertained for the bacteria in the air that Lister attempted to neutralize the danger with carbolic sprays and other means; now the surgeon pays little heed to the air of a well-kept operating room. Instead he ties several layers of sterile gauze over his mouth and nostrils and over his head to guard against particles falling from these sources.

It was one of the great surprises when bacteriologists demonstrated that the expired breath under normal conditions of respiration is sterile.

At one time many, if not most, of the contagious diseases were believed to be air-borne; many observations are on record purporting to prove that contagium may be carried long distances through the air. With the increase of our knowledge concerning the modes of transmission of infection the list of air-borne diseases has steadily dwindled. The theory is reluctantly given up, for it is the easiest method of explaining the spread of the readily communicable diseases. There are only two diseases of man, viz., smallpox and measles, which may possibly be air-borne, in the sense that this term is generally used. Both these diseases are so readily communicable that the virus seems to be "volatile"; it is assumed that the active principle is contained in the expired breath; however, there is no proof of this assumption, and some evidence to the contrary. Further, it is noteworthy that we are still ignorant of the causes and the precise mode of entrance of the contagium in both measles and smallpox. Even in these two diseases the radius of danger is much more limited than was once supposed to be the case.

<sup>2</sup>*Jour. of Med. Res.*, June, 1910, XXII, 3, pp. 461-468.

The more the transmission of the communicable diseases is studied the less the air is implicated. The fact that malaria (bad air), yellow fever, and other diseases are conveyed by mosquitoes has robbed the air itself of false accusations, and given a death blow to miasms, effluvia, and intangible theories. Pettenkoffer insisted that the air became contaminated with poisons that were generated in a polluted soil, and he believed that these emanations were responsible in part for typhoid fever and cholera. Some association between soil, air, and disease still persists in both medical and lay minds, but with a more precise knowledge of the causes and modes of transmission of infections, such as typhoid fever and cholera, the air becomes a negligible factor. Out-of-door air contains relatively few bacteria; further, the dilution is enormous. Most microorganisms pathogenic for man soon die when dried or when exposed to sunlight. Whatever danger, then, resides in the air, so far as living principles of disease are concerned, is found rather in indoor air, and especially in the air of badly ventilated, dusty, and crowded places. Here the danger may be either from the bacteria-laden dust or from droplet infection. In a crowded and stuffy street car, in a poorly ventilated office, or in a closed, close sickroom it would be very easy for the microorganisms of diphtheria, scarlet fever, whooping-cough, measles, pneumonia, influenza, common colds, tuberculosis, pneumonic form of plague, and other infections contained in the secretions from the nose and mouth to be held in the air in sufficient numbers so that exposed persons may contract the disease. This probably occurs more frequently than we are at present inclined to admit.

The radius of danger through droplet infection is quite limited. It is difficult to conceive that infection may be carried long distances in the air and still be dangerous. My own experience indicates that there is practically no hazard in establishing a hospital for contagious diseases upon the high road or even in a thickly inhabited part of the city. In fact, the communicable diseases are not conveyed in the air from ward to ward or even from bed to bed in well-managed hospitals.

Hutchinson found that prodigious bacilli in sputum droplets may be carried almost 2,000 feet when the temperature is low. It therefore seems probable that diphtheria bacilli would persist longer and carry farther in droplet infection in cold weather than in warm weather. This explanation has been given to account for the seasonal prevalence of plague, diphtheria, etc. The two chief ways in which bacteria are transferred through the air are (1) by droplet infection, and (2) by dust. Mouth spray is really a form of contact infection.

Chapin states that many contagious hospitals have been maintained for years with no increase of the disease in the vicinity, as, for instance, at Boston and Providence, R. I. At the Kingston Avenue Hospital in Brooklyn various diseases, as smallpox, measles, scarlet fever, and

diphtheria, are treated in wards only a few feet apart, with no evidence of aerial transference. At North Brother's Island the tuberculosis ward is only about 25 feet from the diphtheria ward, but the tuberculous patients do not contract diphtheria. A number of hospitals for communicable diseases have recently been built with entire disregard of aerial infection. At the hospital of the Pasteur Institute, Paris, the patients are cared for each in a separate ward opening into a common hall. The same nurses go from case to case. In  $2\frac{1}{2}$  years after it was opened in 1900 there were treated 2,000 persons, of whom 524 had smallpox, 443 diphtheria, 126 measles, 163 erysipelas, 92 scarlet fever, and 166 non-diphtheritic sore throat. The only evidence of the transfer of infection was the development of four cases of smallpox and two of erysipelas. In the Hôpital des Enfants Malades in Paris the beds, instead of being in separate rooms, are separated by partitions. Of 5,017 cases there were only 7 cross infections, 6 of measles and 1 of diphtheria. These were attributed to lapses in aseptic precautions. Dr. Moizard thinks that this experience proves that even measles is not air-borne. Dr. Grancher in another Paris hospital has two wards in which there are no partitions, but only wire screens around the beds, simply as a reminder for the nurses. He also insists that measles is probably not an air-borne disease, and that adjacent patients do not necessarily infect one another. At various English hospitals similar methods have been tried with success.<sup>3</sup>

While the air plays a minor rôle in the spread of the infections, bad air plays an important part in reducing vitality and predisposing to disease. This will be discussed presently.

## POISONOUS GASES IN THE AIR

Some of the poisonous gases of the air come from natural sources, as marshes, mines, or decomposing organic matter, but those that concern the sanitarian particularly are the gases which arise from the works of man. These gases are carbon monoxid, ammoniacal vapors, hydrochloric acid, carbon bisulphid, carbureted hydrogen, hydrogen sulphid, etc.

**Carbon Monoxid.**—Carbon monoxid (CO) is a frequent and serious cause of acute poisoning and also of chronic ill health. It has become one of the commonest forms of gas poisoning. Deaths from carbon monoxid in large cities now exceed those from any other poison.<sup>4</sup> It is usually found associated with other gases, especially from the incom-

<sup>3</sup>Chapin: *Jour. Am. Med. Assn.*, Dec. 12, 1908, Vol. LI, pp. 2048-2051.

<sup>4</sup>The total number of cases of gas poisoning in Cook County, Illinois, for 1916 was 501,—nearly 8 per cent. of the entire number of coroner's cases. (*J. A. M. A.*, July 27, 1918, p. 257.)

plete combustion of coal or wood. It is also one of the ingredients of illuminating gas, and is one of the constituents of the gases of coal mines. Burning charcoal gives CO in great abundance, and it is also given off from red hot cast-iron stoves; further, it is found about lime kilns and where open coke fires and braziers are used in confined spaces; also from iron and copper furnaces, the exhaust of gas engines and from many manufacturing processes.

The gases from stoves or furnaces contain 79.7 per cent. nitrogen, 10 to 13 per cent. oxygen, 0.6 per cent.  $\text{CO}_2$ , and 0.3 to 0.5 per cent. CO when formed by the incomplete combustion of wood or coal in closed spaces, that is, with the damper closed. Illuminating gas from coal contains from 6 to 10 per cent. CO; from wood 62 per cent.; water gas, 30 per cent. and more. Gases in coal mines contain from 4 to 10 per cent. CO, from 0.6 to 1 per cent.  $\text{H}_2\text{S}$ , and 53 per cent.  $\text{CO}_2$ . Gases from smokeless powder and gun cotton contain high quantities of CO and are quite dangerous.

For public health purposes the chief sources of CO are leaky gas fixtures, open coal fires, the premature closing of dampers of stoves and furnaces, or defects in apparatus burning coal, spent gases from automobiles and explosives in technical pursuits.

Air containing 0.4 per cent. of carbon monoxid may, in one hour, prove fatal. In higher concentration a person may be overcome at once and death soon ensues. Kinnicutt<sup>5</sup> states that breathing an atmosphere containing 0.3 per cent. of carbon monoxid, for any considerable period, is fatal, and the presence of 0.2 per cent. is capable of destroying life (Haldane). Gréhan found that inhalation of an atmosphere containing 1 part of CO to 275 parts of air was fatal to a dog, and that 1 in 70 killed a rabbit. Less than a gram of CO may kill a man. Breathing an atmosphere containing 0.05 per cent. of CO may cause unpleasant, even serious symptoms (Oliver). Even as little as 0.07 to 0.12 per cent for half an hour will render one quarter of the red corpuscles incapable of uniting with the oxygen. Chronic poisoning with smaller amounts may lead to anemia, depression, psychoneuroses, and other symptoms.

A child having relatively large respiratory exchange for its size is overcome more quickly than an adult. On this account, small animals, such as birds and mice, are overcome more quickly than men. Canaries are always carried by the rescue crews of the Bureau of Mines when carbon monoxid is suspected.

Carbon monoxid or carbonic oxid is a colorless, tasteless and practically odorless gas; it burns with a pale blue flame. Its poisonous action depends upon the fact that it combines with the hemoglobin of the red blood corpuscles to form carbon-monoxid-hemoglobin. This is

<sup>5</sup> *Jour. Am. Chem. Soc.*, 1900, Vol. XXII, p. 14.

a stable compound which, therefore, prevents the hemoglobin giving up its oxygen to the tissues. When present in only small amounts and for long periods of time, the effects of CO may be compensated for by a polycythemia—an increased number of corpuscles taking the place of those disabled. It is commonly stated that CO has a direct destructive action upon the cells of the central nervous system, causing paralysis in acute cases and psychoneuroses in chronic cases. Yandell Henderson, however, denies any direct action because tissue cultures will grow *in vitro* in a concentrated atmosphere of CO.

The symptoms depend upon the presence of CO in the air breathed, the rapidity of breathing, the presence of other gases, and the age of the individual. The quantity of CO present in the air is of more importance than the length of exposure to it.

*Acute Poisoning.*—The individual feels dizzy and complains of headache, noises in the ears, throbbing in the temples, and the feeling of sleepiness and sense of fatigue. There may be vomiting and a sense of oppression at the chest, palpitation, and an inability to stand or walk straight. Convulsions may or may not come on; pupils are dilated and react slowly to light; the face is red; consciousness is gradually lost, but owing to the great loss of motor power the individual, though aware of the danger, is often unable to escape from it. In animals the heart beat at first is slow, while the blood pressure is high; in man the action of the heart is frequently violent even during the stupor. When a man has recovered from the acute effects of carbon monoxid his life is still imperiled for some days to come. He runs the risk of dying as late as 8 days after the accident and then he has still to face the risk of glycosuria, or other serious sequelae.

When a person is removed from the poisonous atmosphere there is slow return to consciousness, but headache, nausea and weakness persist for a long time. In case of continued inhalation of the poison there is a marked dilatation of the peripheral vessels, causing extensive red spots on the skin.

Death occurs from paralysis of the respiratory apparatus. If a case does not terminate fatally, there may be serious sequelae, such as apoplexy followed by softening of the brain, or blisters, decubitus, or paralysis may develop, also chorea, idiocy, or minor grades of psychoneurosis.

The post-mortem appearance, following acute intoxication with carbon monoxid, shows the following: Features placid, face and skin bright ruddy color, both arterial and venous blood bright cherry red, and showing the spectrum of carbon-monoxid-hemoglobin. The muscles, brain, and all organs are more pink than usual. Lungs may be emphysematous, and red patches may be observed on the surface of the abdominal viscera; occasional submucous hemorrhages in the stomach and intestines.

*Tests.*—The presence of carbon monoxid in air may be determined with considerable accuracy with a solution of blood. A few cubic centimeters of normal blood solution are shaken to saturation with the sample of air. A dilute blood solution is yellow; it becomes pink when treated with traces of carbon monoxid. By comparing the color with carmin this method will serve for quantitative purposes.<sup>6</sup> More accurate determinations may be made by the iodine pentoxid method of Seidell.<sup>7</sup>

**Illuminating Gas.**—Illuminating gas may be harmful either from the products of its combustion or, more so, when the unconsumed gas escapes in the household. The two principal illuminating gases used are coal gas and water gas. The poisonous effects of both are due mainly to the carbon monoxid which they contain.

*Coal gas* is made by the destructive distillation of coal. It contains hydrogen, marsh gas, and carbon monoxid, occasionally also ethene, acetylene, and carbon dioxid. A cubic foot of coal gas completely burned gives to the atmosphere about one-half a cubic foot of  $\text{CO}_2$  and about 1.34 cubic feet of water vapor. An ordinary gas jet burns about 6 cubic feet of gas per hour, and thus produces about 3 cubic feet of  $\text{CO}_2$ .

*Water gas* is made by blowing a current of steam through incandescent coke or coal. The water is decomposed into hydrogen and oxygen. The hydrogen passes on and the oxygen unites with the carbon to form carbon monoxid. Water gas so produced burns only with a pale blue flame. It is, therefore, enriched in a carburetor with vaporized petroleum; this furnishes the hydrocarbons necessary to give a luminous flame. Water gas contains about 30 per cent. of carbon monoxid.

One of the most common sources of carbon monoxid<sup>8</sup> in the household is from illuminating gas. Illuminating gas may pass from a broken gas main through the soil into the cellar and thence permeate a dwelling; this is aided by the suction and pumping action of the heating apparatus in the cellar. In passing through the soil illuminating gas may be robbed of its characteristic odor, thus rendering it so much more dangerous because not perceived. The danger from this source is further increased in the winter time and in cities with asphaltum and concrete pavements, because under these circumstances the escape of gas into the air is hindered and the chance of more of it reaching the house through the cellar is favored. An occasional source

<sup>8</sup> See also page 1308.

of CO in the air of houses is through hot-water heaters, using illuminating gas as fuel. The soot gradually collects in these devices and may become incandescent, thus furnishing ideal conditions for the production of carbon monoxid. In the arts CO is formed by passing water vapor over incandescent carbon. I know of one case in Washington where CO from a water heater collected in a kitchenette in such concentration that three persons were overcome upon entering the room and died.

Most coal contains sulphur, which appears in coal gas as sulphuric acid, which is irritating and poisonous. Most of the sulphur compounds in coal gas are removed by processes of purification during manufacture, but, owing to the difficulty of complete removal, 20 grains of sulphur in every hundred cubic feet are generally allowed by law. The sulphur restrictions have recently, but unwisely, been removed in England. In Massachusetts the legal limit has been raised to 30 grains per hundred cubic feet. These changes were brought about by the claims of gas companies that it is much more difficult than formerly to procure coals low in sulphur, so that the processes for the removal of the sulphur have become costly and burdensome.

Illuminating gas is required by law, in Massachusetts and in many other places, to be free from ammonia as well as sulphurated hydrogen, but this is more because of injury to fixtures than because of danger to health.

The effect of these carbonaceous illuminants is to elevate the temperature and increase the moisture of a room. They also add carbon monoxid, carbon dioxid, nitric and nitrous acids, compounds of ammonia and sulphur, marsh gas, carbon particles (soot), acids of the fatty group in small but variable amounts. The following instructive table gives the comparative candle power and also the gases and heat produced by the usual forms of illuminants:

	Quantity Consumed	Candle-power	Oxygen Removed	Carbon Dioxid Produced	Moisture Produced	Heat Calories Produced	Vitiation Equal to Adults
	grains		cu. ft.	cu. ft.	cu. ft.		
Tallow candles.....	2,200	16	10.7	7.3	8.2	1,400	12.0
Sperm candles.....	1,740	16	9.6	6.5	6.5	1,137	11.0
Paraffin oil lamp.....	992	16	6.2	4.5	3.5	1,030	7.5
Kerosene oil lamp.....	909	16	5.9	4.1	3.3	1,030	7.0
Coal gas, No. 5 Batswing burner.....	cu. ft. 5.5	16	6.5	2.8	7.3	1,194	5.0
Coal gas, Argand burner	4.8	16	5.8	2.6	6.4	1,240	4.3

Coal gas, Welsbach incandescent.....	3.5	50	4.1	1.8	4.7	763	3.0
Electric incandescent light.....	lb. coal 0.3	16	0.0	0.0	0.0	37	0.0

Water gas is cheaper than coal gas, and is, therefore, preferred by gas companies. Usually a mixture of the two gases is supplied. Ex-

perience shows that if water gas is properly diluted with coal gas the danger is greatly lessened. Illuminating gas containing 6 per cent. of carbon monoxid is not hazardous. Most cities limit the amount to 10 per cent. In 1890 the 10 per cent. statute was repealed in Massachusetts, and it is since then that the marked increase in illuminating gas poisoning has occurred. There were 1,231 deaths caused by illuminating gas in Massachusetts during the years 1886 to 1909. About one-half of these deaths were suicidal. This only represents the fatalities, and does not take into account the many cases of chronic poisoning which occur in the home and in the industries where much illuminating gas is used.

Sedgwick and Schneider<sup>9</sup> state that the death rate from poisoning by illuminating gas in Massachusetts and Rhode Island has become nearly equal to that of scarlet fever or measles.

Gas pipes in a dwelling should be tested from time to time with a pressure gauge, and minor leaks from faulty stopcocks, from "rubber" tubing used for droplights, etc., should be carefully searched for and corrected. A flaring gas burner is not only wasteful, since it implies the escape of unburned gas, but is also harmful to health. A gas jet should burn steadily without jumping and flaring.

*Methane* ( $\text{CH}_4$ ), also called "marsh gas," "fire damp" or "light carbureted hydrogen," is found in nature as "natural gas" in and about coal and oil regions. Methane is very light compared to air (specific gravity 0.5596), and forms an explosive mixture as soon as it amounts to 1/18th of the volume of the air. Fortunately, the mixture does not ignite readily, but is nevertheless the cause of many accidents in mines. The gas has no odor, is slightly soluble in water, burns with a pale smokeless flame, yielding watery vapor and carbon dioxide—"after damp." Methane forms a large proportion of illuminating gas. It is usually regarded as an indifferent gas, but it probably has slight toxic properties. Haldane found that 5.5 per cent. of methane had no effect on man; 45 per cent. causes slower and deeper breathing, and 70 per cent. endangers life. With 70 per cent. the oxygen is reduced to only 6.3 per cent. and the nitrogen to 23.7 per cent.

Methane is also given off in large quantities from decomposing matter in swamps, sewers and septic tanks. Methane may constitute 70 to 80 per cent. of the gases found in a septic tank. The gases from an Imhoff tank may be used for illumination and heating.

The table on the following page shows the percentage composition of illuminating gases, with the gases of an Imhoff tank, for comparison.

**Other Gases in the Air—Ammoniacal Vapors.**—Ammoniacal vapors irritate the conjunctiva, but have no other evident effect on health in the amounts ordinarily found in the air.

*Hydrochloric Acid Vapors.*—Hydrochloric acid vapors in large

<sup>9</sup>*Jour. of Infect. Dis.*, Vol. IX, No. 3, 1911.

ILLUMINATING GASES: COMPOSITION IN PERCENTAGE<sup>10</sup>

	Imhoff Tank	Natural Gas	Water Gas	Coal Gas
H.....	8.6	1.31	30	47.49
CH <sub>4</sub> .....	84.1	87.75	24	38.67
CO <sub>2</sub> .....	4.6	6.6	....	1.04
N.....	3.1	4.34	2.5	.85
CO.....	....	....	29	6.74

C <sub>2</sub> H <sub>4</sub> .....	....	....	12.5	5.21

quantities are very irritating to the conjunctiva and respiratory mucous membranes. In the alkali manufactures they are sometimes poured into the air in sufficient quantity to destroy vegetation. When in sufficient concentration they may induce bronchitis, pneumonia, and even destruction of lung tissue, as well as inflammation of the eyes.

*Carbon Bisulphid.*—Carbon bisulphid is given off in the vulcanizing of India rubber. It produces headache, vertigo, pains in the limbs, formication, sleeplessness, nervous depression, and loss of appetite; sometimes deafness, dyspnea, cough, febrile attacks, and even paraplegia. The effects seem due to a direct anesthetic action on the nervous tissue.

*Hydrogen Sulphid.*—Hydrogen sulphid is a colorless, transparent poisonous gas possessing the smell of rotten eggs. It is a product of the putrefaction of organic substances, containing sulphur, and therefore found where vegetable or animal matter is undergoing decay. It is also generated by the decomposition of organic matter by anaërobic bacteria in deep lakes and ponds, tainting the water, in which it is soluble, or coming to the surface and tainting the atmosphere where its presence is indicated by the discoloration caused to neighboring dwellings painted with white lead. Small sluggish streams receiving the sewage of towns become defiled with this gas from which source it may be discharged in noticeable quantities as it is carried by the wind in different directions. Hydrogen sulphid is formed spontaneously whenever a soluble sulphate remains in contact with decaying organic matter with deficiency of air. It is also formed directly by the union of sulphur and hydrogen, and indirectly by the action of acids on sulphids; it is found in the gases contained in some ground waters; further, in some mining, smelting, and other industrial processes; and in illuminating gas, which contains traces. Its intense odor enables it to be recognized when present in minute quantities, 1 part in 10,000 being easily noted. It is slightly heavier than air—specific gravity, 1.1912.

*Toxic Action.*—As a toxic agent, hydrogen sulphid stands between hydrocyanic acid and carbon monoxid. Appreciable quantities in the

<sup>10</sup> *Engineering Record*, Febr. 5, 1916.

air may have a toxic action, which is due, in part, to the formation of sulphmethemoglobin, but mainly to a direct action upon the nervous system. The susceptibility of man to this gas varies. Its dangerous nature is fully recognized in all chemical laboratories. The effects of small amounts are not well understood; Thackrah could find no bad effects. On the other hand, Hirt believed it produced chronic poisoning, the symptoms being chiefly weakness, depression, anorexia, slow pulse, furred tongue, and marked pallor.

According to Lehman an atmosphere which contains 0.7 to 0.8 of  $H_2S$  per 1,000 liters of air is dangerous to human life, while air containing 1 to 1.5 per 1,000 destroys life rapidly. Vivian Lewes states that man is killed in one and one-half minutes after breathing air containing 0.2 per cent. of  $H_2S$ . The sudden death of men when working in sewers is sometimes supposed to be due to sulphurated hydrogen.

The symptoms caused by exposure to considerable amounts of hydrogen sulphid are redness and pain of the eyes, nasal catarrh, and irritation of the mucous membrane and bronchi, dyspnea, cough, rapid beating of the heart, dizziness, headache, numbness, and cold perspiration. Sudden exposure to large volumes of the gas causes death with striking rapidity; respiration stops before the heart. Death results from complete paralysis of the central nervous system, and even though persons are rescued, they may subsequently succumb from bronchopneumonia, caused by the irritating nature of the gas.

Autopsies performed immediately after rapid death disclose no changes, not even in the blood. In case of slow death edema of the lungs or pneumonia will be present, and the body has the characteristic odor of hydrogen sulphid. If death comes more slowly asphyxia is added to the nervous symptoms; the blood is dark and its hemoglobin may be altered, while the urine may contain albumin or sugar.

*Hydrogen Sulphid in Sewers.*—Workmen in excavations are sometimes overcome by  $H_2S$ , when a spring containing this gas is tapped. Workmen are also occasionally overcome in the dead ends of sewers, in gate chambers or manholes, and in these cases  $H_2S$  is sometimes said to be the cause of the accident.

Hydrogen sulphid is formed from sewage by the breaking down of protein and also by bacterial action upon inorganic sulphates.

In America, and, so far as known, in Europe, there are no data indicating that this gas ordinarily is present in measurable quantities in sewers. At Worcester it is stated that careful examination of large volumes of sewer air failed to show the presence of either hydrogen sulphid or carbon monoxid. At Lawrence it is also stated that hydrogen sulphid has never been detected in measurable amounts in the gas of any of the septic tanks.

On the other hand, it is known that hydrogen sulphid makes its presence known around a number of septic tanks by the discoloration of lead paint, and even from the odor of the gas, as well as its disintegrating effects upon masonry. Mr. W. Thwaites<sup>11</sup> records from 0.2 to 1.1 per cent. of free hydrogen sulphid per volume and 0.2 to 0.9 per cent. of combined hydrogen sulphid in the sewerage system of Melbourne, Australia. The sewage of this city flows for a distance of about 18 to 25 miles and is applied to sewage farms. Hydrogen sulphid combines readily with basic constituents of sewage and thus differs from methane, nitrogen, hydrogen, and other gases arising from decomposition.

The spent liquors from tannery wastes sometimes contain calcium sulphid, which is used to remove the hair from the hides, and also sulphuric acid which is used in one of the processes of tanning. When the acid meets the calcium sulphid, hydrogen sulphid is evolved, endangering those in the sewers or along the trunk lines. Two fatalities which were attributed to this cause occurred in Stoneham, Massachusetts.

The amount of hydrogen sulphid ordinarily found in "sewer gas" which may escape into houses as a result of defective plumbing, is so small and so dilute as to produce no known symptoms. Hydrogen sulphid is by no means the only malodorous product of the decomposition of sewage; indol, skatol, cadaverin, mercaptan and other ill-defined products are even more offensive than hydrogen sulphid.

*Sulphur Dioxid.*—Sulphur dioxide is extremely irritating and causes bronchitis. Those exposed to the fumes in the bleaching of cotton and worsted goods are frequently fallow and anemic.

## SEWER GAS

Sewer gas, once a hygienic bugaboo, is now not seriously regarded by sanitarians. Sewer gas became the residual legatee of Murchinson's pythogenic theory, namely, that typhoid fever was "produced by emanations from decaying organic matter." People naturally cling to the notion that anything that smells bad must be detrimental to health; sanitarians know however that our sense of smell is a very poor sanitary guide.

Sewer "gas" is nothing more or less than air containing the volatile products of organic decay coming from sewers and drains. Sewer gas is a variable mixture both as to composition and concentration. Some of these gases are more or less poisonous, but not in the great dilution ordinarily found in sewer air. As a matter of fact, the air of sewers is ordinarily freer of dust and bacteria than the corresponding outside

<sup>11</sup> Thwaites, W.: *Tr. Am. Soc. of Civil Eng.*, Vol. LIV, Part E, pp. 214-30.

air, although it may be a little higher in carbon dioxide—10 to 30 volumes per 10,000. It is absurd to regard sewer gas as the cause of diphtheria, typhoid fever, scarlet fever, and other communicable diseases. So far as unpleasant odors are concerned, they are more apt to come from defective drains or unclean and unventilated house plumbing than from a well-constructed sewer. The subject of putrid odors from sewers is a highly complicated one. Odors are due, in most part, to decomposition products, such as hydrogen sulphid, ammonia, indol, skatol, phosphin, mercaptan, phenol, and various acids, such as acetic, butyric, valerianic and other compounds. Workmen employed in sewers and about sewage ordinarily remain hale and healthy. "Sewer gas" as a rule is no more hurtful than the gases and odors a farmer subjects himself to on the manure pile.

Winslow and Greenberg<sup>12</sup> exposed guinea-pigs to strong odors and gases from putrefying feces, and found that there was a reduction in the rate of growth during the first week, but the animals soon became accustomed to the odor and attained after two weeks a normal growth.

Delepine<sup>13</sup> could not detect any influence of sewer air either upon the growth curve of cats, rabbits, and guinea-pigs, or upon their susceptibility to a spontaneous epidemic due to infected food.

**Bacteria in Sewer Air.**—When it was found that there are no dangerous volatile poisons in sewer air attention was focused upon the bacteria; however, Nägeli as long ago as 1877 showed that putrescent liquids kept in the same sealed vessel for over two years did not infect each other. Sir Edward Frankland then showed that lithium carbonate in solution did not contaminate the air, but that when effervescence was produced the breaking of the bubbles on the surface of the liquid carried the lithium a distance of 21 feet up a vertical tube. The inference was that sewage through fermentation or splashing may send bacteria into the air. Pumpelly in 1881 and others since have shown that bacteria are not given off from a liquid if the surface remains unbroken, even though the air may blow over it. In 1893 Miquel began a monumental work upon bacteria of the air. He made routine observations at the Montsouris Observatory, and for four years compared the bacteria in the air of a Paris street with the air of sewers. He found sewer air relatively pure from a bacteriological standpoint. Carnelly and Haldane in 1877 found fewer bacteria in the sewers under the House of Parliament and other places than in the air of adjacent streets. The number of bacteria was largest in the best-ventilated sewers, because these brought the street bacteria along with them. Abbott in 1894 showed that cul-

<sup>12</sup> *Proceed. Soc. Exp. Biol. and Med.*, May 15, 1918.

<sup>13</sup> Report of Sewer Ventilation Committee upon the Effects on Health of the Air of the High Street Sewer in Manchester, 1909.

tures of *B. prodigiosus* are not carried over in bubbles produced by natural fermentation (yeast in a carbohydrate medium), but may be carried a short distance by blowing air at considerable velocity through the culture. He concluded that the danger of bacteria being transmitted from sewage into the air under ordinary circumstances is practically negligible. In 1907 Horrocks revived this question by placing *B. prodigiosus* in the water-closets of a large military hospital in Gibraltar, and recovering them on plates suspended on top of the soil pipes and in manhole openings. His work gave countenance to the views of a number of English sanitarians, who maintain the reality of the danger from this source. Winslow repeated Horrocks' experiments in 1909, using the ordinary sewage of Boston, and by using quantitative methods threw a different light upon Horrocks' conclusions. He found that a vigorous foaming produced very slight bacterial infection of the air—only five *prodigiosus* colonies in 30 liters of air. Further, the infection always remained localized. Generally he found the air of house drains singularly free from bacteria. It, therefore, seems theoretically possible, but very improbable, that infection may take place in this way. Practically the question seems to have little importance. Thus, out of a series of examinations of plumbing systems in actual use, Winslow found intestinal bacteria only four times in 200 liters of air, and these directly at the point of local splashing.

If there is any danger of sewage bacteria coming into our houses, it is rather that they are dragged in by rats, roaches, water bugs, and other vermin that use sewers and drains as highways.

**Accidents in Sewers.**—Workmen who enter parts of a sewerage system are sometimes overcome. Practical sewer men know that the danger is found in the dead ends, gate chambers, manholes, and similar places where the gases can accumulate; also in suddenly relieving an obstruction in a sewer, thus permitting a blast of gases. There are no such dangers in a well-ventilated sewer. Stagnant sewage and sludge, combined with lack of ventilation, form conditions resembling a septic tank, and it is this combination that menaces the workers. A free flow of sewage promotes ventilation and diminishes the chances of gases accumulating.

The principal gases given off from sewers are methane, carbon dioxid, hydrogen, ammonia, and sometimes hydrogen sulphid. None of these gases is particularly poisonous, excepting the last. When carbon monoxid is found in sewer air it does not come from the decomposition of the sewage, but from illuminating gas which leaks in. Many analyses of sewer air in many different places show that hydrogen sulphid is usually absent.

The following table gives the percentage of gases found in settling tanks in various cities of the United States:

SETTLING TANK GASES: PERCENTAGE OF CONSTITUENTS <sup>14</sup>

	Methane	Nitrogen	CO <sub>2</sub>	O	H
Atlanta.....	84.1	3.1	4.6	.4	8.6
Chicago.....	84.9	6.2	8.6	....	...
Urbana.....	81	6.1	12.3	.13	...
Columbus.....	83.5	9.3	8.1	....	...
Worcester.....	57.7	32.5	8.2	1.2	...
Lawrence.....	78.9	16.3	3.4	.5	...
Manchester....	73	16	6	....	5

The danger in entering manholes, gate chambers, or dead ends of sewers is from: (1) illuminating gas which has leaked in; (2) asphyxia on account of an accumulation of carbon dioxid and methane; (3) trade wastes containing volatile substances, such as petroleum products from garages, dry cleaning establishments, oil works, or gases caused by spent liquors from tanneries, chemical works, etc.; (4) poisonous gases, as hydrogen sulphid, which are said sometimes to accumulate in appreciable amounts.

*Explosions in sewers* are due to illuminating gas from leaks; benzin, naphtha, and gasolene from garages, dyeing and cleaning works, and also from lithographic works; hydrocarbon oils used by railroads to prevent freezing of switches, and other inflammable and explosive substances. The gases may be fired by open lights carried by workmen, by the sparks from trolley cars or fire engines passing over manholes, or by lightning. The prevention is constant ventilation; traps for catch basins, and furnishing workmen with electric lights or safety lamps to replace ordinary lanterns.

### ILLUSTRATIVE CASES OF DEATH BY SEWER GAS

*Case No. 1.*—The main sewer of the town of Revere, Mass., discharges into the sea near the southerly end of Revere Beach. In order that the sewage might not discharge on the incoming tide, a covered tank was built near the seashore into which the sewage collected, and the tank was constructed of such capacity that the sewage would not rise as fast as the tide. On the other hand, the bottom of the tank was somewhat above low tide. In consequence, the flow of the sewage was shut off by a tide gate when the tide was high for several hours and subsequently discharged automatically as the tide went down and the sea had fallen below half tide. Two men were sent to clean the tank, which was done by stirring up the sediment with a stream from a 2½-inch fire hose at about the time the tank would discharge. It appears that trouble

<sup>14</sup> *Engineering Record*, Febr. 5, 1915.

had been previously experienced by gases in the tank chamber at such times, and the man in charge was warned of this, but he neglected to warn his helper whom he sent down into the tank; the helper was overcome and drowned. In the lawsuit the main question raised was whether the town agents exercised due care in the matter, and the jury decided that they did not, and awarded full damages to the plaintiff. No evidence was presented to show the character of the gas which doubtless caused the accident except that the evidence showed that the gas was odorless. It was generally believed by those interested in the case that the gas was  $\text{CO}_2$ .

*Case No. 2.*—On August 6th Henry G. Parker,<sup>15</sup> an able and valued member of the staff of the Engineering Department of Los Angeles, lost his life while inspecting a weir chamber of the outfall sewer connecting the Los Angeles sewer system with the Pacific Ocean. Mr. Parker and Mr. Derby entered the chamber to test the working of the gate, which was raised and lowered by means of a hand-wheel and screw. In attempting to raise the gate they were overcome with the foul air and were required to retreat to the surface three separate times. The third time Mr. Parker suddenly fell a distance of twenty feet, and the body slipped from the sluiceway and was sucked into the sewer before rescue could be accomplished. Death was doubtless due in large part to the effect of the gases and the fall of twenty feet, and not to drowning, as very little water was found in the lungs. Just what gases were present is not stated.

*Case No. 3.*—During the pumping out of a manhole in Charleston, S. C., in May, 1911, a small boy was sent down to remove some chips which threatened to obstruct the suction pipe. He succumbed almost immediately. One of the workmen went down to rescue him; he also became unconscious. A third party, with a rope tied around him, went to the rescue of the two. When taken from the manhole, the small boy was dead, and the second man was unconscious. The symptoms reported by Dr. Jager and Dr. Jerdey were those of hydrogen sulphid poisoning. A qualitative analysis of the air of the manhole made at a later time showed the presence of hydrogen sulphid and no appreciable quantities of carbon monoxid. It is assumed in this case that the hydrogen sulphid in the manhole probably accumulated and became concentrated in the bottom of the manhole, although it was recognized that other gases may have contributed to the gravity of the condition.

*Case No. 4.*—A laborer went into an intercepting sewer on Market Street in Lynn, Mass., to inspect it, and after he had proceeded into the sewer about 250 feet his lantern exploded, covering him with blazing oil. The cause was assumed to be illuminating gas that had leaked into the sewer from some unknown place. The man had his hair singed and

<sup>15</sup> *Engineering Record*, Aug. 28, 1909, LX, 9, p. 252.

his face badly blistered, and was partly overcome. The sewer was not ventilated, nearby manholes having been closed.

**Prevention of Accidents in Sewers.**—To prevent accidents in manholes, and other parts of the system where sewer gases may collect, it is advisable for men always to work in pairs, and to be ready with rope, tackle and tripod in case of emergency. Accidents may be prevented by clearing out cul-de-sacs where sewer gases are likely to collect, before the men enter such places. This may be done by an air blast, but as this is usually not at hand the same purpose may be accomplished by a water spray having a good head and volume. This stirs up the air and ventilates the pocket.

Other precautions to determine the presence of dangerous or irrespirable gases consist in lowering a candle, a safety lamp, or small animals (canary or mouse) in a cage.

**Ventilation of Sewers.**—Sewers cannot be constructed airtight on account of the numerous openings into them. The tension of the air in sewers is generally not very different from that of the atmosphere outside. The movement of the air is generally in the direction of the flow of the current. The simplest plan of ventilation is by means of a shaft from the top of the sewer to the surface of the street or road above, where the opening of the shaft should be covered by an iron grating. These openings are usually placed at intervals of 100 yards or so. This system, which is in common use, has been much criticized, mainly on account of the fact that the objectionable gases are discharged more or less immediately under the noses of passers-by. To meet this objection it has been proposed, and actually come about in some places, to locate tall iron shafts at suitable intervals to permit the discharge of air and gases at a level well above the roofs of houses. As a matter of fact, if sewers are well constructed, have sufficient fall and flow of water, there will be no accumulation of foul gases. One of the main causes of decomposition is due to dead ends. These should not be tolerated by the engineer in charge of the sewage department. Recently an agitation has been started to solve this question of sewage ventilation by advocating the abolition of the intercepting traps on the house drains between the sewer and the house, thus converting every house drain and every soil pipe into so many sewer ventilators. There are many objections to this plan, as it would destroy the drain isolation between the houses, which is now possible from the sewer, and from the neighboring houses of the district.

## CHAPTER V

### FRESH AND VITIATED AIR

#### THE BENEFITS OF FRESH AIR

Fresh air is nature's tonic. It stimulates digestion, promotes assimilation, improves metabolism, strengthens the nervous system, and increases our resistance against some diseases. It is a common experience that fresh air gives us a general feeling of well-being. Much of the benefit of an outdoor life comes also from the exercise, diversion, sunshine, and other factors. The stimulating effect of outdoor air varies considerably with the temperature and movements of the air. The ceaseless variations in the rate of cooling, evaporation and absorption of radiant energy, in outdoor conditions, relieve us of monotony and stimulate tone and metabolism. Cold air is especially stimulating, and much of the good of sleeping out of doors is perhaps secondarily due to the tonic action of cold. Sleeping out of doors or with open windows atones for much bad air during the daytime. However, the good results of fresh air may be neutralized by undue exposure to cold, especially in the young, the aged, and the feeble—or even in robust individuals not properly protected.

“We may write and talk as much as we please about the horrors of bad air and the importance of fresh air, but we should never induce people to sit in cold drafts and shiver for the sake of pure air, and, in fact, we would not want to do it ourselves” (Macfie). Extremes in this as in all matters hygienic are to be avoided. It is important that those who sleep out of doors or sit out should be warmly clad and sufficiently fed.

#### THE EFFECTS OF VITIATED AIR

The effects produced by an atmosphere vitiated by the breath and other exhalations from human beings may be divided into acute and chronic. The acute effects are usually lassitude, headache, vertigo, nausea, vomiting, and even collapse. In extreme cases death may ensue. The chronic effects, so far as is known, include anemia, debility, and disturbances of digestion. Prolonged exposure to vitiated atmospheres also influences nutrition and metabolism, depresses vitality, and

lowers the resistance to certain infections, especially to the pyogenic cocci, the tubercle bacillus, the pneumococcus, and to the microorganisms causing common colds. It is often difficult, especially in the poorer classes, to know how much is due to bad air and how much to crowding, poor food, overwork, loss of sleep and rest, worry, and other inflictions of poverty. There is plenty of evidence to show that men living in insufficiently ventilated barracks and other habitations have a high death rate. The lower animals under like conditions in crowded and poorly ventilated stables also have a high mortality. The statistical evidence of the English Barrack and Hospital Commission, published as long ago as 1861, shows that men living a considerable portion of their time in badly ventilated rooms have a higher death rate than those having well-ventilated rooms, other conditions being about the same.

The high morbidity and mortality in crowded places are due, in part at least, to the favorable conditions for the spread of the communicable diseases, and must not be laid entirely to the effects of vitiated atmospheres.

**Some Extreme Cases.**—The acute and fatal effects caused by breathing a seriously vitiated atmosphere, under unusually severe conditions, are well illustrated by the three following instances:

After the battle of Austerlitz 300 Austrian prisoners were shut into a prison in a small cellar, and 260 were killed by the impure air in a few hours.

In the tragedy known as the Black Hole of Calcutta, the military prison of Fort William, January 18, 1756, 146 adults were shut into a room only 18 feet square and with but two small windows on one side to ventilate it. They were shut in at 8 P. M., and within an hour some were dead, and when the door was opened at 6.20 next morning only 23 were found to be alive. One of the survivors gives the following description of the horrors of the night: "At this period so strong a flavor came from the prison that I was not able to turn my head that way for more than a few seconds at a time. Everybody except those at the windows now grew outrageous and many delirious. By eleven o'clock greater numbers were dead or dying, and those living were in an outrageous delirium and others quite ungovernable. A steam now arose from the living and the dead, which most awfully affected those who were still alive. At six o'clock next morning it came to the ears of the Indian governor the havoc death had made in this fearful place, and he ordered their release. At 6.20 there came out of this living grave 23 *half-dead creatures*, being all that remained of the 146 souls who had entered the Black Hole prison, and these were in such a condition that it seemed very doubtful whether they would see the morning of another day. Many of the survivors developed putrid fever and boils. The remaining 23 were poisoned by exhalations from their own lungs and bodies."

An almost equally terrible tragedy took place on the steamer *Londonderry*, going between Sligo and Liverpool. The episode is thus described by G. Henry Lewes ("Physiology of Common Life"):

"On Friday, December 2, 1848, she left for Liverpool with two hundred passengers on board, mostly emigrants. Stormy weather came on, and the captain ordered every one below. The cabin for the steerage passengers was only 18 feet long, 11 feet wide, and 7 feet high. Into this small space the passengers were crowded; they would only have suffered inconveniences if the hatches had been left open; but the captain ordered these to be closed, and—for some reason not explained—he ordered a tarpaulin to be thrown over the entrance to the cabin and fastened down. The wretched passengers were now condemned to breathe over and over again the same air. This soon became intolerable. Then occurred a horrible scene of frenzy and violence, amid the groans of the expiring and the curses of the more robust; this was stopped only by one of the men contriving to force his way on deck, and to alarm the mate, who was called to a fearful spectacle: seventy-two were already dead, and many were dying; their bodies were convulsed, the blood starting from their eyes, nostrils, and ears."

The foregoing instances are exceptional, and for practical purposes may be regarded simply as the results of suffocation. The usual conditions never approach such extremes, but are, nevertheless, important, for they may be serious. We must first consider the question why an atmosphere vitiated by the presence of human beings produces ill effects.

Three explanations have been offered: (1) increase of carbon dioxid and diminution of oxygen; (2) poisons in the expired breath; (3) physical changes of the air. Each of these explanations will be considered separately.

#### **The Effects of Increased Carbon Dioxid and Diminished Oxygen.—**

According to the older theories, the sensations of discomfort, arising in inclosed places, had their origin either in an excess of carbon dioxid or an insufficiency of oxygen. Thus, in the early experiments of Claude Bernard (1857) animals were confined in atmospheric air and in mixtures both richer and poorer in oxygen than atmospheric air. He explained the poisonous effects of carbonic acid when respired to be due to the fact that it deprived the animal of oxygen. Similar results were reported by Valentin and by Paul Bert. Richardson in 1860-61 found that a temperature much higher or lower than 20° C. had the effect of shortening very considerably the lives of animals confined in an unventilated jar. Pettenkoffer in 1860-63 cast the first serious doubt on the correctness of these theories. He believed that the symptoms observed in crowded, ill-ventilated places were not produced by the excess of carbonic acid nor by a decrease in the proportion of oxygen in the air. He further did not believe that the impure air of dwellings was directly

capable of originating specific diseases, or that it was really a poison in the ordinary sense of the term, but that it diminished the resistance on the part of those continually breathing such air.

Hermans<sup>1</sup> showed that an atmosphere containing only 15 per cent. of oxygen and as much as 2 to 4 per cent. of carbon dioxid may not be harmful. On removing the carbon dioxid there was no great discomfort, even when the oxygen was reduced to 10 per cent. The air of certain breweries examined by Lehmann<sup>2</sup> contained 1.5 to 2.5 per cent. of carbon dioxid, and men worked continuously in this for years without any ill effects. The CO<sub>2</sub> occasionally rose to 6 per cent. and more, but this amount produces panting and distress. It is now generally admitted, upon the testimony of numerous experimenters, that an atmosphere containing as much as 3 per cent. of carbon dioxid and as little as 15 per cent. of oxygen has no toxic effects and produces no disturbing symptoms. In the most poorly ventilated rooms the carbon dioxid never reaches this amount, especially when produced by respiration alone. It is unusual to find 0.5 per cent. In the most crowded rooms the oxygen rarely reaches as low as 20 per cent. In mines the oxygen is often deliberately kept down to 17 per cent. with the object of avoiding dust explosions. It is, therefore, plain that we must look to other causes for the effects of vitiated air. See also pages 867 and 872.

**Poisons in the Expired Breath.**—In 1863 Hammond believed he demonstrated the presence of organic matter, because when vitiated air is passed through potassium permanganate, it decolorizes that strong oxidizing agent. Hammond confined a mouse under a jar in which the CO<sub>2</sub> was taken up by baryta water as fast as it was formed and the moisture absorbed by calcium chlorid. Nevertheless, the mouse died in 40 minutes. The observation was repeated a number of times, and death ensued invariably in less than one hour. Brown-Séquard and D'Arsonval in 1888-9 claimed to be the first to demonstrate poisonous bodies in the expired breath. They condensed the moisture in the exhaled breath, which was injected into the veins of rabbits. Death usually took place in a few days, sometimes in a few weeks. They believed from this that they had discovered a volatile organic poison of the nature of an alkaloid, similar to Brieger's ptomains. These experiments were repeated with variable results, but in 1889 they reported ingenious experiments in which they obtained additional evidence in support of their former statements. Rabbits were confined in a series of jars connected with rubber tubing, permitting a constant current of air to be passed. The animal in the last jar received the air from the lungs of the animals in the other jars. This animal died after an interval of some hours,

<sup>1</sup>Hermans: "Ausschaltung organischer Substanzen durch den Menschen," *Archiv f. Hyg.*, 1883, I, 1.

<sup>2</sup>Lehmann: "Untersuchung über die langdauernde Wirkung mittlerer Kohlensäuredosen auf den Menschen," *Arch. f. Hyg.*, 1899, XXXIV, 335.

and the animal in the next jar was the next to die. The first and second animals usually remained alive. When absorption tubes containing concentrated sulphuric acid were placed between the last two jars, the animal in the last jar remained alive while the one in the jar just before was the first to die. These results confirmed their belief in the existence of a volatile poison absorbed by the sulphuric acid. Haldane and Smith repeated the experiments of Brown-Séquard and D'Arsonval, using five bottled mice. They continued the exposure for 53 hours without ill effects to the mice. Beu in 1893 also repeated these experiments, and came to the conclusion that acute poisoning through the organic matters contained in the expired air was not possible, and that the death of the animals was due to changes of temperature and accumulation of moisture in the jars. Rauer in 1893, also Lübberd and Peters, concluded from similar experiments that there are no organic poisons in the expired air. In fact, Merkel stands almost the only sponsor for the correctness of the conclusions of Brown-Séquard and D'Arsonval, and with some slight changes of technic he was unable to get uniform results.

Lehmann and Jessen in 1890 collected from 15 to 20 c. c. of condensed fluid per hour from the breath of a person exhaling through a glass spiral laid in ice. This fluid was always clear, odorless, neutral in reaction, and contained slight traces of ammonia with good teeth; more with poor teeth. Inoculation of this condensed fluid into animals gave negative results. Many other experiments, including von Hoffman-Wellenhof, Lehmann and Jessen, Haldane and Smith, Billings, Weir Mitchell, and Bergey, have shown that the fluid condensed from the breath is no more toxic than distilled water, when injected into animals. This has strengthened the general belief that poisonous bodies are not present.

In 1894 Brown-Séquard and Davis reported further experiments in which they inoculated over one hundred animals with the condensed fluid of respiration, and not only confirmed their former statements, but were unable to understand the failure of other experimenters, and emphatically reaffirmed that the breath contains a volatile poison and that the death of animals under experimental conditions is not due to an excess of carbon dioxid nor a deficiency of oxygen. These experiments were repeated by Billings, Mitchell, and Bergey<sup>3</sup> in 1895, who came to the conclusion that the ill effects of vitiated atmosphere depend almost entirely upon increased temperature and moisture, and not on an excess of carbon dioxid or bacteria or dust of any kind. They admit that the cause of the musty odor in unventilated rooms is unknown.

<sup>3</sup>Published by Smithsonian Institution, 1895. Contains a summary of the literature to date, with references to authorities.

In addition to reducing potassium permanganate, it has been shown that the breath contains traces of ammonia and traces of hydrochloric acid. These have their origin in decaying teeth and decomposing particles of food or other putrefactive or pathological changes occurring in the upper respiratory passages. The ammonia and hydrochloric acid exist in such small quantities that they have no practical bearing upon the question under consideration.

Weichardt<sup>4</sup> calls attention to the fact that putrefactive processes go on in the excretory products of the respiratory tract, especially in older persons. He states that the bronchial mucus of corpses contains a poison resembling kenotoxin (the toxin of fatigue). When injected into laboratory animals it produces a lowering of temperature, a slowing of respiration, and death. According to Weichardt, fluids condensed from the expired air and then concentrated, when injected into mice, produce like results. This investigator also evaporated some of the condensed moisture from the expired breath and obtained a weighable residue (9 milligrams from 10 c. c.). This he regards as partly organic matter. As further proof that the organic matter in the expired breath is active, he obtained from the expired breath of a tired old man the condensed fluid which he then concentrated. This concentrated fluid has a distinct inhibitory effect upon the oxidizing power of the ferments in blood, as shown by the guaiac indicator. Also by means of the epiphanin reaction Weichardt considers that he has demonstrated protein-split products in the vitiated air of a room. He concludes that substances having such important biological power should not be longer overlooked. These results lack confirmation, and the methods are open to criticism.

Rosenau and Amoss<sup>5</sup> demonstrated the presence of minute traces of non-poisonous protein matter in the expired breath through the reaction of anaphylaxis. The first injection into guinea-pigs of the fluid, obtained by condensing the moisture of expiration, is harmless, but the animals become sensitized, so that they react to an injection of human blood serum after an interval of several weeks. These results lack confirmation, in fact Weisman and also Winslow obtained negative results. In any event there is no evidence that the expired breath contains a poisonous substance.

**Physical Changes in the Air.**—Owing to the failure of chemistry to demonstrate the cause of the ill effects produced by a vitiated atmosphere, attention has recently been focused upon the physical changes, such as the increase in temperature, increase in humidity, and the stillness of the air in a poorly ventilated room. Hermann in 1883 first

pointed out that heat and moisture were probably the factors that produced the harmful effects of bad air rather than its chemical composition. Important experiments were carried out about five years ago in the Institute of Hygiene in Breslau by Heymann, Paul, and Erclentz. Flügge,\* who was then the director of the institute, has admirably summarized and interpreted the results as follows:

Paul placed healthy individuals in a cabinet of 3 cubic meters' capacity, where they were kept for a variable time up to four hours, and until the carbon dioxid had risen to 100 or 150 parts in 10,000—an accumulation of gaseous excretion practically never developed under ordinary conditions. In these experiments no symptoms of illness or discomfort developed so long as the temperature and moisture were kept low. Tests of the psychic fatigue of these individuals by means of the esthesiometer and ergograph, or by means of computations, gave negative results throughout, under similar conditions of temperature and moisture. Tests in a crowded schoolroom were similarly negative. Erclentz made the same observations on diseased persons. Those suffering from emphysema, heart diseases, kidney diseases, etc., with the exception of a few peculiarly susceptible anemic and scrofulous school children, bore the highly vitiated air for hours without any evidence of bodily or mental depression.

The results were very different, however, when the temperature and moisture of the air of the cabinet were allowed to increase. At 80° F. with moderate humidity, or at from 70° to 73.5° F. with high humidity, practically all persons began to show depression, headache, dizziness, or a tendency to nausea. The susceptibility was not alike for all. School children reacted slightly and emphysematics slightly, while those with heart troubles were most susceptible. By means of certain objective signs of heat stagnation—the surface temperature of the forehead and the temperature and moisture of the clothed parts of the body—it was determined that subjective symptoms appeared only when the surface temperature reached a certain height. This was, for healthy people, 93° F. to 95° F. on the forehead; for the more susceptible and diseased, 89.5° to 91.5°; and with the moisture of the skin increased by 20 or 30 per cent. Under these conditions the normal dissipation of body heat is interfered with, and it is under these conditions that

\* Flügge: *Ztschr. f. Hyg.*, 1905, XLIX, 363. Crowder: *Archives of Internal Medicine*, Jan., 1911, Vol. VII, pp. 85-133. symptoms appear which are in every way similar to those developed in overfilled and "stuffy" rooms.

Now, when these people in the cabinet suffering from such symptoms were allowed to breathe the fresh outside air through a tube, such air being raised to the temperature and relative humidity of that within, it gave them no relief whatever; nor did the internal air produce any symptoms when breathed through a tube by one outside of the cabinet. But the symptoms of discomfort and illness experienced by the person within could be almost immediately relieved either by drying the air of the cabinet or by cooling it, or by putting it in rapid motion by means of a fan, without any chemical change being made in the air. The effect of these measures is simply by purely mechanical means to enable the body to throw off its heat more rapidly, and thereby all symptoms disappear; heat stagnation is the cause of the discomfort.

From the long series of experiments, carried out with great care as to all the details of observation and control, it is concluded that all of the symptoms arising in the so-called vitiated atmosphere of crowded rooms are dependent on heat stagnation in the body, and that the thermic conditions of the atmosphere, its moisture, and its stillness are responsible for the effects. To change any one of these elements is to change the rapidity of the loss of heat. If the change is such as to increase this loss, comfort is restored. It is also considered proved beyond any reasonable doubt, by their own as well as by previous research, that there is no gaseous excretion into the surrounding air, either from the breath or from other sources, deserving of the name of poison.

Angelici,<sup>7</sup> working independently at about the same time, concurs in these opinions; and Reichenbach and Heymann<sup>8</sup> later determined that objective evidence of heat stagnation in the body always precedes the development of subjective symptoms of discomfort under natural conditions, in the same way it does under the artificial conditions of the cabinet.

Leonard Hill<sup>9</sup> of England also has confirmed these general results and conclusions.

The New York Commission on Ventilation<sup>10</sup> found that the power to do mental or physical work, measured by the quantity and quality of the product by subjects doing their utmost, is not at all diminished by a room temperature of 86° F., with 80 per cent. relative humidity, but the inclination to do physical work is diminished by high temperatures.

<sup>10</sup> *Amer. Jour. of Public Health*, Vol. V, February, 1915, No. 2, p. 85.

The only effect of stagnant air, even when it contains twenty or more parts of carbon dioxid, is slightly to diminish the appetite.

The experiments seem to indicate that overheated rooms are not only uncomfortable, but produce well marked effects upon the heat regulating and circulatory systems of the body and materially reduce the inclination of occupants to do physical work. The most important effects of even a slightly elevated room temperature, such as 75° F., are sufficiently clear and important to warrant careful precautions against overheating. A warm atmosphere, especially if moist and still, causes a rise in bodily temperature and this in turn disturbs metabolism, decreases working power, and causes early onset of fatigue. It is now clear that most of the symptoms caused by poorly ventilated rooms are due to the prevention of heat loss owing to the physical conditions of the air. See also pages 904-913.

**Reinspiration of Expired Air.**—By this phenomenon is meant the immediate reinspiration of a portion of our expired breath. This occurs quite commonly, in fact may almost be regarded as a normal accompaniment of respiration during the major part of our lives. Lehmann<sup>11</sup> and also Heymann<sup>12</sup> determined the CO<sub>2</sub> of the inspired air, compared this with the CO<sub>2</sub> of the surrounding air, and from the difference computed the proportion of the breath which was reinspired. They found this proportion to vary greatly. It was sometimes more than 6 per cent., but dropped to zero in the open air, and in a breeze of 3 meters per second. Crowder<sup>13</sup> confirms these observations and extends them much further. He shows that under many conditions the air about the face contains much more CO<sub>2</sub> than the surrounding air. The path of the expired air may roughly be seen by watching the course of smoke blown from the nostrils. The expired air leaves in a cone-shaped expansion, part of which lies quite close to the body, and then rises slowly by convection currents. Inspiration follows expiration immediately, therefore every chance is offered for some of the expired air to be again drawn in, except when facing a breeze of from 200 to 300 feet per minute, or when walking, riding, or fanning. When the back is turned to a breeze a little of the expired air is often reinhaled in spite of the current.

The position of the head influences the amount of air rebreathed. Thus Crowder has shown that while sitting upright the reinspiration was 2.3 per cent.; lying down with a pillow tilting the head forward, 1.3 per cent.; lying flat, head thrown back, none at all. In the ordinary position in bed, with the head on the side and flexed, with pockets or

dead spaces for the air to stagnate, there will be a greater retention of expired air. This occurs especially when the head sinks into a soft pillow.

It may be concluded that when one lives indoors and remains quiet he will immediately rebreath from 1 to 2 per cent. of his own expired air; in bed it will be more, from 1 to 5 per cent., and even 10 to 18 per cent., depending on the position in which he lies. Nor does sleeping in the open insure "pure" air, for breathing, especially when one buries his head between pillows and bedclothes for the sake of warmth. On the other hand, it is plain that "a little extension of the dead space beyond the tip of the nose is of no consequence."

### SUMMARY

It is now perfectly plain that the ill effects resulting from a vitiated atmosphere are not due to an increase of carbon dioxide nor to a diminution in oxygen. Upon this point all are agreed. The general consensus of opinion also excludes poisonous bodies in the expired breath as a factor.

Sanitarians are satisfied, with the evidence presented, that most of the discomfort is due to physical changes only. If a normal heat interchange can be maintained between the body and the air the symptoms which are commonly attributed to poor ventilation do not develop. According to this view the vital element of the ventilation problem becomes that of regulating the temperature, moisture, and motion of the air. When the air is still we are surrounded by an "aërial envelope" with a temperature and moisture resembling the open air on a hot and humid day. The symptoms caused by crowd poisoning, such as oppression, malaise, headache, vertigo, nausea, vomiting, and even collapse, indeed resemble those of heat exhaustion.

Metabolism is reflexly retarded by a warm aërial envelope, and stimulated by cool moving air, the consumption of oxygen by the tissues and the production of  $\text{CO}_2$  by them being much less in warm air than in cold air.

Even those who look upon the physical changes in the air as the sole cause of the discomfort rather than the possibility of chemical changes admit that a certain amount of fresh air must be supplied. Flügge himself urges that life in the open should be more and more resorted to, but he would have the motive correctly understood, not that the chemical condition of inside air is harmful, but that it is the overheating of rooms that causes disturbances of health. Flügge states that one should go into the open not because he may breathe chemically purer air, but because its almost constant motion carries away the body

heat and causes a beneficial stimulation of the skin and reflexly brings about a heightened cell activity that aids in the development of sturdy health. The chemistry of air and "crowd poisons" have little or no part to play in the explanation of outdoor benefits or of indoor discomforts. These are both dependent upon physical conditions, and their explanation rests with the physics of heat interchange between the body and its surrounding medium.

There is some danger in regarding the ill effects of poor ventilation as due to thermal and other physical factors alone. According to this theory it is only necessary to keep the temperature and moisture down and keep the air in motion; a closed office with an electric fan would take the place of any system of ventilation. There is already a clamor against the laws requiring fresh air in workrooms, based upon Flüggé's views. This is a natural corollary of Flüggé's views. If rebreathing the same air is not hurtful, the ventilation of living rooms may be greatly simplified by simply keeping the physical conditions of the air within the limits of comfort. Furthermore, a great economy would be effected. It is, however, not scientific to insist that the chemical changes in a vitiated atmosphere may be disregarded, because we cannot at present demonstrate immediate relationship between cause and effect; neither is it safe to deny dogmatically the existence of injurious substances in a vitiated atmosphere simply because in the present state of our knowledge chemistry has failed to demonstrate them, and because most of the symptoms may be explained upon disturbances of thermic interchange.<sup>14</sup>

Furthermore, most of the observations have been based upon short exposures; it is very probable that a decrease in mental and physical efficiency would result from a prolonged exposure to a vitiated atmosphere, even though it were kept dry and cool. The improvement in appetite, nerve vigor, blood quality, and muscular tone which follows open air treatment, even in the rich and well-fed, shows the paramount importance of fresh air.

## CHAPTER VI

### VENTILATION AND HEATING

#### VENTILATION

The problem of ventilation is apparently a very simple one; all that is required is to furnish a never-ending stream of fresh air from the inexhaustible supply without to replace that which is constantly being vitiated. To do this under the artificial conditions of house and factory life is often extremely difficult, and under certain circumstances practically impossible. Further, the problem of ventilation must take into account not only the quantity of air, but its physical condition, in order that the human machine may operate at the highest level of health and efficiency.

Ventilation must serve a number of purposes and comply with a number of conditions before it can be considered satisfactory: (1) it must bring pure air from without in order to dilute and remove the products of respiration, as well as other sources of vitiation; (2) it must maintain the air within the room at a proper temperature and humidity, and, further, must keep the air of the room in gentle and continuous motion; (3) it must remove the gases, odors, bacteria, dust, and other substances that contaminate the air of inclosed spaces; (4) it must dilute and remove the impurities produced by the burning of gas, candles, lamps, and other sources.

The problem of ventilation is physical rather than chemical, cutaneous rather than respiratory.

The purpose of ventilation is not to bring outdoor conditions indoors; the art of ventilation consists in adapting indoor conditions to indoor life. Indoor life is necessary in order to perform the delicate manipulations which cannot, as a rule, be effectively conducted outdoors. Indoor life, then, involves quiet and protection from sudden changes or extremes.

It is a simple mechanical problem to condition the air of an apartment. The ventilating engineer finds no difficulty in regulating the temperature and humidity within narrow limits, and in furnishing definite quantities of fresh, moving air. To maintain these conditions, however, the doors and windows must be kept shut. Herein arises the

first difficulty between the theory and the practice of ventilation, for it is plain that the simplest and often the best way to ventilate a room is through open windows. The second difficulty arises from the fact that the conditions within and without the room to be ventilated are not constant. The principal factors here concerned are the force and direction of the wind, changes of outdoor temperature, and, to a less degree, movements within the room. It is, therefore, much easier to maintain constant air conditions in a sub-basement than in a room exposed to wind and weather. Air conditioning is now an established engineering science, and the engineer is prepared to supply any kind of air that is desired.

The efficiency of any system of ventilation must be measured by the results obtained at the breathing zone. It matters little what the composition or the condition of the air is near the ceiling, provided the heated, moistened, and vitiated aerial blanket which surrounds us is constantly removed and replaced with a fresh supply properly conditioned.

Ventilation is far from satisfactory if the air brought into the room is smoky, dusty, or bacteria-laden, or if it is contaminated with gases or odors from cellars or surroundings. Attention should, therefore, be given to the sources of the air, and it is always an advantage to wash or filter it. There is a practical limit to the amount of fresh air that may profitably be forced into a room, especially warmed air in the winter time. Ventilation and heating naturally go hand in hand.

The belief is growing that it is not dangerous to rebreathe air, and the view is spreading that the hygienic value of ventilation for the purpose of maintaining a chemically pure atmosphere in dwellings, schools, and hospitals is not so great as is commonly supposed. According to this view it is more important to ventilate in the interest of the heat economy of the body, by the establishment of a suitable temperature and air movement, and by the regulation of the humidity in the atmosphere. The established facts, that the principal causes of the ill effects of vitiated air are due more to the heat and humidity and stillness of the air than to changes in its chemical composition, have led some hygienists to recommend rebreathing the air, provided the physical conditions are kept favorable.

Satisfactory ventilation should not only take into account the physical conditions of the air, but also demands a generous supply of fresh air in order to keep the chemical composition within reasonably normal limits. Clean air in motion and of proper temperature and humidity is necessary to indoor comfort.

The rigor of a cold climate makes of its inhabitants a house-dwelling race. Under these conditions houses are commonly overheated, if not by fire and steam, then by the heat of the inhabitants' bodies. When

people do this they complain of poor ventilation, regardless of whether the air supply is large or small.

The problem of ventilation is immediately related to clothing, bathing, diet, exercise and other factors in personal hygiene that stimulate the vasomotor mechanism and make it vigorous and effective. In other words, the problem of ventilation concerns itself chiefly in conditioning the air so as to favor the heat regulating mechanism of the body.

Dwelling houses are usually constructed with little regard for ventilation. It is desirable that adequate provision should be made for the ventilation of every house that is built. This requires just as much care and forethought as the system of heating the house, or furnishing it with water, gas, electricity, plumbing for the disposal of wastes, and other household conveniences. Whatever system of ventilation may be adopted, it is wise to flush rooms frequently with fresh air and flood them with sunshine. This helps to blow out the accumulated dust and bacteria, to oxidize organic matter that collects as a film on all surfaces, to diminish odors, and generally to purify the apartment.

In all systems of ventilation the factor of faithful and intelligent operation is essential to success. No method is fool proof and no method will work by itself. Even window ventilation requires watchful attention of those in charge of individual rooms. "Constant vigilance is the price of pleasant and wholesome air conditions" (Winslow).

**Air Washing.**—The process of air washing consists of passing the air horizontally through a chamber in which water is falling in drops as rain, or into which it is sprayed. The sprays are obtained by forcing the water out of perforated pipes or through nozzles placed across ducts. When the sprays intersect they are said to form a "curtain." The object is to bring the air and water into intimate contact. Besides the washing chamber there are heating or tempering coils in the ducts, or in a separate chamber, and devices for controlling the temperature. The water used for washing is circulated by means of a pump so that it may be used over and over in the spray chamber for a considerable time.

The New York State Commission on Ventilation found that air washing does not remove body odors.

Washing takes out many of the impurities in the air, as bacteria, molds, dust, epithelial scales, particles of various descriptions, also some odors and gases, but not  $\text{CO}_2$ . Washing is the best way to cleanse the air as it imitates nature's process through a rain shower. If desired, the water may be cooled in the summer time so as to influence the temperature of the air. Several forms of air washers are on the market, essentially similar in principles, but differing in details of construction.

**Recirculation.**—The cost of heating large volumes of cold air has naturally stood in the way of efficient ventilation of schools and factories during the cold weather. Another question has been the low indoor

relative humidity produced by heating outdoor air to a comfortable room temperature. Washing and recirculating the air overcomes both of these objections because it furnishes an ample supply of conditioned air in motion. The method has attracted favorable attention. Naturally there must be a limit to the continued use of the same air, but ordinary leakage and the use of a certain percentage of outside air prevent the concentration of any substances not removed by the washer.

The only advantage of washing and recirculating the air lies in the great saving of fuel in cold weather. At the gymnasium of the International Y. M. C. A. College at Springfield, it was estimated that a saving of from 40 to 50 per cent. of coal resulted from recirculating the air. The success with the method at Springfield was probably due to the enormous air supply of the gymnasium. The method has many objections for schools and workshops. The New York Committee on Ventilation was quite unable to wash the air enough to remove body odor. There are factors still imperfectly understood.

Recirculated air is not equal to outside air washed. The great objection is that washing the air does not remove odors; it is therefore not very practical. Recirculation may be subject to abuse, and if used must be carefully watched.

**Vitiation by Respiration.**—An adult individual at rest breathes at the rate of about seventeen respirations a minute. At each respiration about 500 c. c. (30.5 cu. in.) of air pass in and out of his lungs. The air in the lungs loses about 4 per cent. of oxygen and gains 3.5 to 4 per cent. CO<sub>2</sub>. The nitrogen remains unchanged. In addition the expired air is raised in temperature to nearly that of the blood, 98.4° F.; it also contains much aqueous vapor.

The amount of CO<sub>2</sub> which is given off by an adult male person at rest can be calculated from the above figures, and will be found to be 0.71 cubic foot in one hour. Thus:—

$$\frac{17 \times 30 \times 60}{1728} = 17.7 \text{ cubic feet breathed per hour.}$$

$$4 \text{ per cent. of } 17.7 = 0.71 \text{ cubic foot per hour of CO}_2.$$

From actual experiment it has been determined that an average adult gives off 0.9 of a cubic foot of CO<sub>2</sub> during gentle exertion, and possibly as much as 1.8 during hard work. The adult female gives off about one-fifth less under similar circumstances, and an infant is said to give off about 0.5 cubic foot of CO<sub>2</sub> per hour. In a mixed assembly at rest, including male and female adults and children, the CO<sub>2</sub> given off per head is, therefore, taken as 0.6 of a cubic foot.

**Vital Capacity of the Lungs.**—The volume of air inspired and expired depends on the rate and extent of the respiratory movement, but in an adult man of average size and vigor about 500 cubic centi-

meters of air are inspired and expired during quiet breathing. This volume of air is known as the *tidal air*, and since the total volume of air in the lungs is about 3,500 c. c., it is evident that in normal breathing a large amount of air—3,000 c. c.—remains in the lungs at the end of expiration. The air which remains behind is known as *stationary air*.

By forced expiration about half of the stationary air, i. e., 1,500 c. c., can be expired, and this portion of the stationary air is known as the *supplemental or reserve air*, while the final 1,500 c. c., which no effort can expel, is known as the *residual air*. The total of 3,500 c. c. of air in the chest, then, at the end of ordinary inspiration is made up as follows:

Tidal air.....	500 c. c.
Stationary air { Supplemental or reserve.....	1,500 c. c.
Residual air.....	1,500 c. c.
	<hr/>
	3,500 c. c.

When, however, inspiration is forced, another 1,500 c. c. of air, known as *complemental air*, can be inspired, making altogether 5,000 c. c.

The total amount of air (complemental, tidal, supplemental) which can be inspired after forced expiration is known as the "respiratory capacity" or "vital capacity" or "extreme differential capacity," and the amount varies considerably according to height, weight, vigor, age, etc.

Peabody and Wentworth<sup>1</sup> furnish the following standards for the vital capacity of the lungs of normal men: For men over 6 feet tall, 5,100 c. c.; between 5 feet 8½ inches and 6 feet, 4,800 c. c.; between 5 feet 3 inches and 5 feet 8½ inches, 4,000 c. c. In women of the same height, it is about one-fifth less.

Vital capacity is a good index of vigor, endurance and reserve power.

**Dead-space Air.**—With each breath, we take back into the lungs the air contained in the nose and larger bronchi—the "dead-space" air. This dead-space air constitutes about one-third of the whole volume of quiet inspiration, and not less than one-tenth of deep breathing. To all intents and purposes it is expired air which is constantly re-inspired. Rebreathing of the ordinary dead-space air is a normal and conservative process; it prevents pure cold air from entering the lungs and reducing the CO<sub>2</sub> below the amount required for stimulating the respiratory center; it makes of breathing a regular and continuous rather than an irregular and interrupted function. Douglas and Haldane have recently shown that the volume of the dead-space, instead of being a fixed quantity, is automatically altered so as to give greater or less resistance to the air-flow to and from the lungs with changing exertion. They go

<sup>1</sup>Arch. Int. Med., Sept., 1917, pp. 433 and 443.

so far as to state that rather marked variations may occur; and, while the mechanism is not fully understood, they think the regulation is as perfect as is that of the vasomotor mechanism for controlling the blood flow.

**Factor of Safety.**—Bernard and Mantoux<sup>2</sup> have shown that the lungs are capable of performing the respiratory function even when the capacity is reduced to one-sixth of the normal. Furthermore, we should remember that the possibility of increase in the depth of inspiration is 400 to 500 per cent., and that by changing the rate and the completeness of expiration the alveolar ventilation may be increased considerably more than 1,000 per cent. From this great margin of safety it is easy to understand why a slight increase of  $\text{CO}_2$  in the inspired air falls far below the limits of our conscious effort. From the experiments of Haldane and Priestley<sup>3</sup> an actual increase of 100 per cent. in the pulmonary ventilation passes almost unnoticed. The factor of safety which Meltzer<sup>4</sup> has so well described as belonging to all well understood physiologic processes, is here a very generous one.

**The Amount of Air Required.**<sup>5</sup>—Omitting from consideration the question of temperature and moisture, a certain amount of pure air is necessary for good ventilation. This amount is determined from the amount of carbon dioxid taken as an index of the impurities from respiration and combustion, and may be ascertained either by direct observation or from physiological data. The accepted amount of pure air required per person per hour is from 2,000 to 3,000 cubic feet. The external air contains 3 parts of  $\text{CO}_2$  per 10,000 (0.03 per cent.), and the permissible limit for indoor air is placed at from 6 to 10 parts. The volume of air in itself is not as important a factor in ventilation as the necessity for the maintenance of air movement to facilitate evaporation and the elimination of heat. It is interesting to note that it requires just about as much air to regulate heat interchange as to dilute the  $\text{CO}_2$  to permissible limits. The amounts necessary to remove odors and dust are about the same as that required to keep the  $\text{CO}_2$  within

reasonable limits. The amount of air needed in good ventilation, therefore, remains about the same as formerly, but our reasons for supplying it have changed.

It has been found from actual observation that an adult in an air-tight compartment will vitiate the air as follows:

In a room	3,000	cubic feet	CO <sub>2</sub>	= 0.06	per cent.	in 1 hour
" " "	2,000	"	"	= 0.07	"	" " " "
" " "	1,500	"	"	= 0.08	"	" " " "
" " "	1,200	"	"	= 0.09	"	" " " "
" " "	1,000	"	"	= 0.10	"	" " " "

The same results may be obtained from physiological data. Thus, the average adult expires 0.6 cubic foot of CO<sub>2</sub> per hour. The difference between the permissible limit, 0.06 per cent., and the amount of carbon dioxid in the air, 0.03 per cent., is 0.03. It follows that the amount of fresh air required per hour by an adult to keep the CO<sub>2</sub> down to 0.06 per cent. may be determined from the following equation:

$$0.03 : 0.6 :: 100 : x$$

$$x = 2,000 \text{ cubic feet}$$

If the normal amount of carbon dioxid in the air is taken as 0.04 instead of 0.03, the result is 3,000 cubic feet, the amount generally accepted, which, however, is somewhat in excess—as it should be. This does not mean that there should be 3,000 cubic feet for each person in an inhabited room, for it is sufficient if the air-space is 1,000 cubic feet, provided, of course, the air is changed three times an hour.

The same results may be obtained by using the formula:

$$\frac{E}{P} = D$$

E=the amount of carbon dioxid exhaled by one person in one hour; the general average for an adult being 0.6 cubic foot.

P=the amount of added CO<sub>2</sub> permitted, stated in cubic feet; or 0.06—0.03=0.03 per cent., or 0.0003 cubic foot.

D=the required delivery of fresh air in cubic feet per hour.

$$\frac{E}{P} = D, \text{ or } \frac{0.6}{0.0003} = 2,000 \text{ cubic feet.}$$

The primary value of E in this equation varies with different conditions.

A male adult	(160 pounds) exhales 0.72 cubic foot of CO <sub>2</sub> per hour
A female adult	(120 pounds) exhales 0.60 cubic foot of CO <sub>2</sub> per hour
A child	( 80 pounds) exhales 0.40 cubic foot of CO <sub>2</sub> per hour
Average	0.60

These values vary also with rest or work. Thus, factories or workshops where men are actively employed need more air proportionately. In light work a man weighing 160 pounds exhales 0.95 cubic foot, while at hard work 1.84 cubic feet, of CO<sub>2</sub> per hour.

$$\text{The formula suggested by DeChaumont is } D = \frac{A}{B - C}$$

A=quantity of CO<sub>2</sub> given off per hour per person=0.6 cu. ft.

B=proposed permissible maximum quantity of CO<sub>2</sub> per 1,000 cu. ft.=0.6 per 1,000.

C=amount of CO<sub>2</sub> present in 1,000 cu. ft. of fresh air (0.3 cu. ft. per 1,000 cu. ft.).

D=amount of fresh air required per head each hour to maintain the standard B expressed in thousands of cu. ft.

$$\text{Then } D = \frac{A}{B - C} \text{ or } \frac{0.6}{0.6 - 0.3} = \frac{0.6}{0.3} = 2,000 \text{ cu. ft.}$$

of air needed per head per hour.

In case of individuals doing light work and giving off 0.95 cu. ft. CO<sub>2</sub> per hour, then

$$D = \frac{0.95}{0.6 - 0.3} = 3,166 \text{ cu. ft.}$$

This is a convenient formula, for it may be used not only to determine the amount of fresh air required, but, knowing the other factors, the amount of cubic feet of fresh air that has been admitted to a room per head may be determined. Further, probable conditions of the atmosphere of a room into which a known amount of fresh air has been supplied can be determined by finding the value of B, thus:

$$B = \frac{A}{D} + C$$

**Standards of Purity—Efficiency of Ventilation.**—There is no single standard by which the purity of the air or the efficiency of ventilation can be determined. We must know at least five factors: (1) the temperature; (2) the humidity; (3) the movements of the air; (4) the amount of CO<sub>2</sub> it contains; (5) dust, bacteria, gases, etc. In a general way it may be stated that the best results are obtained when the temperature is between 62° and 68° F.; the moisture not above 50 per cent. relative humidity (the wet bulb under 70° F.); the movement gentle, without draft; CO<sub>2</sub> not in excess of 6 parts per 10,000; and, finally, freedom from excessive dust, bacteria, gases, etc. Even where all these

factors are found satisfactory there is still one test that must be made in order to be sure that our ventilating system is nowhere at fault—that is the clinical test. Persons occupying the room should suffer from none of the well-known effects produced by air in poor condition. The room should be free from unpleasant odors. If our tests seem right, but the air seems close, something must be wrong with the tests. The evidence of our senses and clinical experience cannot be disregarded.

Where any ventilating device is installed it is readily possible to measure, by means of the anemometer, the amount of air passing through inlets or outlets, but it is often difficult to trace the course of the air in the room. The measured volume of air passing through inlets and outlets does not necessarily determine the efficiency of ventilation in maintaining a continuous renewal of the air at the breathing zone.

The volume of fresh air entering the breathing zone may be estimated with considerable accuracy by determining the proportion of  $\text{CO}_2$  which this zone contains. The air supplied is inversely as the respiratory contamination. It may be computed from the following equation:

$$A = \frac{vp}{x-N}$$

$v$ =the  $\text{CO}_2$  produced by one person; that is, 0.6 cubic foot per hour.

$p$ =the number of people in the room.

$x$ =the proportion of  $\text{CO}_2$  per cu. ft. in the inside air.

$N$ =the proportion of  $\text{CO}_2$  per cu. ft. in the outside air (0.0003).

$A$ =the air supplied to the room in cubic feet per hour.

$$A = \frac{0.6 p}{x-0.0003}$$

It will be seen in this equation that  $vp$  represents the  $\text{CO}_2$  produced by occupants and  $x-N$  represents the respiratory contamination.

In such computations, as also in the direct measurement of air supplies, it is the averages which are most important. From average contamination we may find average air supplies. Erroneous conclusions are very likely to be drawn from single determinations.

Another method of determining the efficiency of ventilation is intentionally to vitiate the air of a room, and then, after a lapse of a certain time, find how far ventilation has removed the carbon dioxide. The amount of air which has entered the room may be found by the formula:

$$C = 2.303 m \log \frac{P_1 - a}{P_2 - a}$$

$C$ =amount of air which has entered; 2.303 is a constant.

$m$ =capacity of the room.

$P_1$ =the amount of carbon dioxid originally present (found by experiment).

$P_2$ =amount of carbon dioxid present after vitiation.

$a$ =amount of carbon dioxid in the outside air.

**The Size and Shape of the Room.**—These are exceedingly important factors in any system of ventilation. It at once becomes evident that a man in a diving suit with a good circulation of fresh air is better off than occupants of a spacious but poorly ventilated apartment in which the air has become vitiated through long occupancy. The air in a small cabin on a steamship may be infinitely better than the air in a large room of a country home. A ratskeller in the sub-basement may, with a modern system of ventilation, have much better air than that found in a department store with acres of floor space and high ceilings. In other words, a small space is sufficient if properly ventilated; a large space inadequate if improperly ventilated.

The size of rooms for dwellings and workshops is somewhat of an economic question, but they should be large enough to allow the air to be replaced two or three times an hour without causing perceptible drafts. The minimal space, in accordance with this standard, is about one-third the quantity of air required per hour; that is, from 700 to 1,000 cu. ft. per person. The amount of space naturally varies with dwellings, factories, schools, theaters, prisons, hospitals; also with the length of time the room is occupied and the nature of the work there carried on. Thus, in hospitals where ordinary cases are cared for, from 1,800 to 2,000 cu. ft. of air is desirable for each patient, while no less than 2,500 cu. ft. should be allowed for each fever patient. Soldiers in barracks are allowed 600 cu. ft. per head, and the limit for lodging houses is usually fixed at from 300 to 500 cu. ft. The U. S. Emigration Law requires 500 cu. ft. per head in the steerage. In figuring the amount of air space in a room allowance should be made for furniture, projecting surfaces, and other objects which diminish the available space. The table on page 976 from Parkes and Kenwood shows the attempts made by Great Britain to fix the minimum space allowed per head by legislation.

A little consideration, however, will show that such regulation of space is by itself of little value. Unless there be movement of air, space alone is futile. However large the space may be, the air will become impure unless fresh air circulates through it, and however small the space the air may be kept pure by sufficient circulation.

As the result of many analyses that have been made by Haldane and Osborne, they found that the carbon dioxid bears no relation to

the amount of air space under practical conditions. In fact, the most highly vitiated air found was in a room with an air space of about 10,000 cu. ft. per person.

It is not alone the air space but the shape of the room that influences ventilation. It is a mistake to suppose that a lofty room is, therefore, an airy room, for a stratum of warm vitiated air soon occupies the upper portion of such a space, and, so far as good air is concerned, has the effect of lowering the effective height of the ceiling to the top of the door or nearest outlet. Anyone may convince himself of this fact by getting up on a stepladder in a room with a high ceiling, improperly ventilated, and occupied for some hours. The upper stratum of air in such rooms is frequently stifling. Ordinarily 12 feet is high enough for the ceiling of school rooms, museums, hospitals, etc., and 9 feet for the rooms of private dwelling houses. Where there is little or no movement of the air it soon becomes offensive, no matter what the height of the ceiling.

Floor space is more important than height. The necessity for an abundant floor space is shown by the fact that a small inclosure with four high walls and without a roof, if crowded, speedily becomes oppressive. In fact, the four walls are not necessary to demonstrate this, for

“crowd poisoning” in the open air upon a still, warm day is a common experience. According to Harrington, when the allowance is only 500 cubic feet per inhabitant, the floor space should be 42 square feet ( $8\frac{1}{2} \times 5\frac{1}{2}$ ). In the English barracks the soldiers are allowed 50 square feet of floor space. For school rooms the British Educational Code requires 120 cubic feet per child in average attendance and a floor space of 10 square feet.

**Inlets and Outlets.**—Whether a room is to be ventilated by natural or mechanical means, proper inlets for the fresh air and outlets for the vitiated air must be provided. No general statement as to the best size and position of these openings will apply under all circumstances.

Knowing the velocity of the incoming air, the area of the inlets may be proportioned so as to permit the movement of the necessary amount of air. The size of the openings under specified conditions is, therefore, a matter of simple arithmetic. In measuring the effective area of inlet and outlet tubes allowance must be made for friction and for the guards or fretwork which protect the openings. These often diminish the effective area about one-half.

In order to provide the air supply of 30 cubic feet per minute, the inlet registers in any room should have a total area equal to 0.1 square foot per capita. The air ducts must be so constructed as to lead the air evenly to the different parts of the building. Each room should be controlled independently by individual ducts and dampers.

It is usually better to admit the incoming air into a large apartment through a number of openings rather than through one large one; the same holds true of outlets. Outlets should be about the same size as inlets and should be placed with reference to them.

All air ducts tend to become soiled with dust and soot and should, therefore, be guarded with wire gratings, or other protecting devices, and they should also be cleaned periodically; further, it should be borne in mind that ventilating ducts are favorable highways for mice, roaches, and vermin. Inlets opening upon the floor are objectionable, as they collect unusual amounts of dirt and dust, which are then blown into the room.

Whether the air is to be admitted near the floor and taken out near the ceiling or *vice versa* is a question much discussed among ventilating engineers. Various possibilities are shown in the diagram, Fig. 99. The natural course of the warmed vitiated air is upward, and it would seem that the upward system has advantages over the downward system. However, a little study will soon convince one that if the incoming air is warm it will rise at once, and the maximum efficiency will be lost at the breathing line, which, after all, is the essential stratum of air in the room. A good arrangement under certain circumstances is to have the inlet above and the outlet below—both upon the same side of

an inner wall. For crowded spaces the best system is doubtless the upward plan, which takes advantage of the natural currents. When this plan is used, the air should be admitted to various parts of the room; in theaters, under each seat.

Outlet ventilation may be arranged by placing a bell cover or glass globe over the gas lights and conveying the heated air thence to the outer air by means of ascending tubes. This not only removes the products of combustion, but, if the outlet tubes have a sufficient area,

FIG. 99.—THE POSITION OF INLETS AND OUTLETS, AND THEIR RELATION TO THE AIR CURRENTS IN A ROOM.

affords a very good system of ventilation. An automatic system of taking the air out of a room may also be provided by placing a shaft either around the chimney flue or against one side of it. The column of heated air in the ventilating duct will rise and draw the vitiated air out of the room with which it is connected. The same may be accomplished by placing a steam jet or a gas burner within the ventilating duct to create a draft.

Ventilating ducts usually extend up the walls of the building through the roof, and should be in as direct a line as practicable. The openings upon the roof may be protected by an umbrella-like covering against rain, or they may be cowled to prevent down drafts. It appears that

none of the exhaust cowls cause a more rapid current of air than prevails in an open pipe under similar circumstances.

Too little attention has been paid in the past to the cleanliness of the air supplied to our buildings. Fresh air inlets are often located with the grossest disregard for the quality of the incoming air. It is not uncommon to see them placed on the sidewalk level; or facing a vacant piece of ground that is swept by clouds of dust; or where smoke, the spent gases from automobiles, or objectionable odors may be taken in.

Crowded buildings and dusty city streets will often render it impossible to secure clean air from the outside atmosphere without resorting to artificial purification.

**External Ventilation.**—Model city planning should provide streets of sufficient width, and should regulate the height of buildings and also limit the extent upon which the land may be built, so as to allow a free circulation of air about all structures and admit a flood of sunshine for at least a few hours during the day. Some of our metropolitan streets resemble canyons rather than city thoroughfares. Crowded tenements, facing upon narrow streets with

FIG. 100.—WINDOW VENTILATOR.

shafts for courts and backing almost directly upon the houses in the rear, and further surrounded by tall buildings which prevent the free movements of the outer air, and shut out the sunshine, should be prohibited, whether used as dwellings or workshops. In such places the ground stays moist, the air becomes stagnant, natural ventilation is greatly retarded, and the conditions upon a hot, still, moist day in summer become almost intolerable.

Generous parks, which are the lungs of a great city, should be scattered throughout the residential and business sections; playgrounds, boulevards, and small open areas treated as parkings not only beautify but help to ventilate a city and add to the comfort, happiness, and health of its inhabitants.

**Natural Ventilation.**—Natural ventilation depends upon openings, such as doors and windows, also upon the air that comes through the pores of plaster, brick, and stone and through floors and ceilings and through the cracks and crevices about window frames, etc.

Natural ventilation depends mainly upon three principal factors:

(1) perflation and aspiration; (2) gravity or thermal circulation; (3) diffusion of gases. These factors constantly operate, whether in the presence or absence of any mechanical system. In fact, most schemes for mechanical ventilation are simply an application of these natural forces.

Perflation is simply the blowing of the air into the room as a result of the movement of natural air currents. Aspiration is the sucking action of the wind which draws air out of a space that it is blowing

FIG. 101.—DIAGRAMMATIC SKETCH OF VARIOUS PROVISIONS FOR VENTILATION.

Lewis, Philadelphia, Blakiston, 1911.)

across. Thus, a wind blowing across an open tube carries along with it some of the air in the upper part of that tube. This causes an upward movement of the air in the tube. The same phenomenon takes place when wind blows by a window. The aspirating action of air is well demonstrated in the construction of an ordinary atomizer.

The air is kept in almost constant motion through changes in temperature. Warm air expands, is therefore lighter, and rises. This is a familiar phenomenon in the hot-air balloon. Thermal circulation, though often imperceptible, is constantly in operation, especially in occupied rooms. Even in calm weather there is considerable ventilation

owing to differences in temperature, and hence differences in pressure between the air of the room and the outside.

More air than is commonly supposed enters or leaves a room through the cracks about doors and windows and other crevices. From the standpoint of natural ventilation it is, therefore, not advisable to have windows fit too snugly. The use of weather-strips, tongue and grooved metal strips, and similar devices to keep out the cold air saves coal bills, but is a considerable hindrance to natural ventilation.

Under certain conditions very considerable amounts of air pass through the building materials used in the construction of walls, floors, and ceilings. Ordinary mortar is most permeable, then comes brick, then sandstone, next plaster of Paris, while enamel and tile are impervious. Under a pressure of 108 millimeters of water the following amounts of air pass in one hour through one square meter of:

Mortar .....	3,264	liters
Plaster of Paris.....	146	"
Bricks .....	312-1,396	"
Sandstone .....	426- 496	"

A pressure of 108 millimeters of water is equivalent to the pressure of a strong wind. The amount of air that will pass through porous materials varies, of course, with the temperature, moisture, and other factors.

Märker and Schultze, in their researches on the spontaneous ventilation of stables, found that the following interchange of air occurred per hour over one square yard of free wall at 9.5° F. difference of temperature:

With walls of sandstone.....	4.7	cu. ft.
Quarried limestone.....	6.5	" "
Brick .....	7.9	" "
Tufaceous limestone.....	10.1	" "
Mud .....	14.4	" "

It is possible to force sufficient air through an ordinary brick to deflect the flame of a candle on the other side. This demonstration is usually accomplished by coating the edges and exposed portions of the brick with sealing-wax and arranging glass funnels on either side. Air forced with a bellows through one funnel may be measured either as to its amount or velocity as it comes out of the opposed funnel.

Natural ventilation is better in winter than in summer, owing to greater differences in temperature. It may be almost *nil* on a hot calm day. Too much moisture in the air of a room settles upon the surfaces and thus stops the pores of building materials, and also prevents the escape of carbon dioxid. Rain has a similar effect on the outside. An ordinary brick will soak up a pint of water. Ventilation through the walls is also hindered by oil and enamel paints and by wall-paper.

Outside obstacles, such as excessive foliage and narrow streets, are also considerable factors.

Natural ventilation may be greatly favored by simple devices. This may be demonstrated by placing a lighted candle in a bottle with a narrow neck. The flame soon dies out, but by placing a partition in the neck of the bottle, so that the products of combustion will escape on one side and the fresh air enter upon the other, natural ventilation proceeds so that the candle remains lighted. There are numerous simple devices that may be placed at the top or bottom of windows which favor the entrance of fresh air or the exit of vitiated air. An arrangement shown in Fig. 100 gives very satisfactory results. One of the upper window panes may be valved or fitted with a fan to permit the entrance of fresh air or the exit of vitiated air. A somewhat similar arrangement used at Fairfield, Conn., is shown in Fig. 102. Openings in ceilings, ridged ventilators, Sheringham's valves, Ellison's bricks, Tobin's tubes, and Stevens' drawer-ventilator are all useful accessory devices to aid natural ventilation.

Ellison's bricks are bricks with conical perforations, the widened end of the conical opening debouching on the interior of the wall. The holes through the bricks are about  $\frac{2}{10}$  inch in diameter externally and  $1\frac{1}{4}$  inches internally.

Tobin's tube consists of a large upright tube, about 5 or 6 feet high, which conducts outside air into the room through the wall.

The Sheringham valve is a small vertical flap door in the wall near the ceiling, balanced by a counterpoise, and hinged so as to fall forward toward the room; it is cased in at the sides and front, so that the current can only pass upward.

Stevens' drawer ventilator is like a drawer lacking its back. It is made to fit into a hole in the wall in such a way that when the drawer is shut the hole is airtight, and when the drawer is open air can enter.

Hinckes-Bird ventilator is made of the opening between two ordinary window sashes when the lower is raised, and the lower opening closed by means of a specially high sill or by an accurately fitting block of wood.

These various devices should be protected with valves so that they may be regulated. Sometimes it is advisable to provide gauze or cotton filters to keep out the dust.

Natural ventilation is greatly aided by means of warming the air in the outlet duct. The best example of this is the open fireplace, or other devices for warming the air in outlet tubes already referred to.

In dwelling houses, where there is no overcrowding, natural ventilation through cracks and crevices, through walls and windows, is ordinarily sufficient for practical purposes.

Wherever possible, open windows are the best and simplest means

of ventilating a room. Any system of mechanical ventilation at best is costly and frequently unsatisfactory. Open windows are cheap and adequate, but the limitations and disadvantages of natural ventilation are obvious, and, therefore, we are frequently required to resort to mechanical means.

*The Fairfield System.*—An ingenious and simple system of modified window ventilation, devised by Mr. S. H. Wheeler of Bridgeport, Conn., and first installed at the Sherman School, Fairfield, Conn., eliminates the disadvantages of the ordinary natural ventilation while retaining some of its peculiar advantages. According to this plan fresh air is admitted through the windows, but direct drafts are prevented by placing slanting window boards on the sashes so that the incoming air is deflected upward and mixed with the general good air of the room. This incoming current is furthermore tempered by placing the radiators used for direct heating under the windows and by making these radiators large enough to extend over the entire width of all the windows. Finally, a duct is provided for the egress of warm, vitiated air passing from near the ceiling of each room to the outer air, the upward current in this duct being maintained by the temperature difference between the outdoor and indoor air.

In industrial establishments where crowding is not great the same general principle has been applied by providing special air inlets to individual rooms with heating coils placed directly in front of them.

*The King System.*—An interesting system of ventilation, known as the King system, is in use in cow stables, which secures much better air conditions than those to which human beings are frequently exposed. Louvred openings at the ridge pole furnish an exit for the warm, vitiated air, while fresh air is admitted through ducts in the walls. These ducts open to the outside at the bottom of the wall and to the inside of the stable four or five feet above the floor, the inflowing current of air being induced by the difference in temperature between the stable and the outer air.

FIG. 102.—FAIRFIELD SYSTEM OF WINDOW VENTILATION.

**Mechanical Ventilation.**—All “artificial” systems of ventilation depend upon one of three methods: (1) plenum system, which consists in the mechanical propulsion of air into the room; (2) the vacuum system, which consists of the mechanical extraction of the air out of the room; (3) a combination of the plenum and vacuum systems.

Air may be propelled into a room either by means of a warming apparatus or by mechanically propelling the air by means of rotary fans. Every heating apparatus is secondarily a ventilating device, especially hot-air furnaces, and the direct-indirect systems in use with hot-water or steam pipes. Stoves, open fireplaces, and similar heating arrangements are also good ventilating devices in that, if well constructed, they take out large quantities of air from the room.

For the mechanical propulsion of air either fans or “blowers” are used. These may be run by electricity, gas, or steam power. The air is forcibly driven through ducts to where it is wanted. Without this system of mechanical ventilation the great office buildings, basement restaurants, large passenger steamships, and other modern structures would not be habitable.

If dependence is placed solely upon drawing the vitiated air out of a room we are leaving to chance where the fresh air is coming from to replace it. In other words, it is impossible when the so-called vacuum system alone is used to control the source of the fresh air and insure its purity. Exhaust systems of ventilation are therefore of value only in connection with a positive air supply. As a rule, all well-ventilated structures depend neither upon the plenum nor the vacuum systems alone, but combine the two.

A complete plenum system consists of (1) screens which strain out dust and large particles, (2) a fan to force the air through the system, (3) tempering coils to heat the air to a moderate degree—50° to 70° F., (4) spray chambers to humidify and wash the air; (5) baffle plates to remove excess moisture, finally (6) heating coils to bring the temperature of the air to the final point desired.

The disadvantages of the mechanical systems of ventilation are that they are expensive as to first installation and as to maintenance; furthermore, they are most effective when the doors and windows of the room are kept closed. The advantages are that they are effective in all kinds of weather, and require less space for the air ducts than natural ventilation.

## HEATING

Heating and ventilation go hand in hand. A large share of the cost of heating is chargeable to ventilation, hence, if ventilation is overdone, it is an unnecessary expense. The artificial warming of

houses has a similar action to clothing. "Burning fuel in the furnace saves fuel in the human machine." It especially saves the strain upon the metabolism of the young, the old, and the feeble. The tendency in winter is to wear too much clothing indoors. This results in coddling—that is, loss of vasomotor tone of our peripheral capillary circulation, from the constant bathing of the skin in a still, warm, moist layer of air. This in turn results in susceptibility to drafts and liability to colds. It is quite unnecessary to wear heavy winter clothing in rooms and offices properly heated and ventilated. Dependence should be placed on warm overcoats when going out of doors.

Most of our American houses are overheated with abnormally dry air in the winter time. This is a mischievous combination. It causes excessive evaporation from the skin and mucous membranes, which gives rise to a feeling of chilliness. It also causes dryness of the skin and mucous membranes, irritation of the throat, and thus predisposes to colds and respiratory infections. Warm dry air does not give the same sense of warmth and comfort afforded by a cooler moist air. Thus, air at 62° to 65° F. and a relative humidity of 70 per cent. feels warmer than air at 70° to 72° F. and a relative humidity of 50 per cent. or less. Furnace heat, hot-water, and steam pipes tend to dry the air, and thus it becomes necessary to overheat our offices and houses before they become comfortable.

Heat is measured by the *British thermal unit* (B. T. U.), which is the quantity of heat required to raise the temperature of a pound of pure water one degree at its point of maximum density, 39° F. The *French thermal unit* is the Calorie and is the amount of heat required to raise one kilogram of water one degree centigrade at corresponding temperature (4° C.). One calorie equals 3.968 B. T. U.

Heat travels by *radiation*, *conduction*, and *convection*. All three routes are constantly in operation in any system of heating. Thus, with an open fireplace the heat radiates in straight lines to the nearest objects, where they are absorbed or reflected, just as light passes through space independent of the atmosphere. That is why our face toasts and our back freezes before an open fireplace. The heat absorbed by any object passes through that object from particle to particle by conduction. Most metals are good conductors; air is a very poor conductor of heat. Convection is the process by which heat is communicated through gases and liquids as a result of their mobility. Thus, the air is warmed by our bodies, by hot-water pipes, and by all heated objects, and therefore rises and establishes convection currents.

There are five main methods of heating: (1) open fires; (2) stoves; (3) hot air furnaces; (4) hot-water or steam pipes; (5) electricity. The control of the temperature of a building is more a question of management than of the system used.

**Open Fires.**—The open fireplace heats mainly through direct radiation. It has the advantage of being cheerful and a good ventilator. It has the disadvantage of being wasteful and very unequal if depended upon as the chief source of heat.

Parkes and Kenwood estimate that, in an ordinary medium-sized sitting room with an ordinary fire, from 10,000 to 15,000 cu. ft. of air are drawn up the chimney in an hour, the current being generally from 3 to 6 ft. a second. "As ventilating agents," say Notter and Firth, "the best types of open fireplace cause some 2,600 cu. ft. of air to pass up the flue per pound of coal consumed, or the passage of about 18,000 cu. ft. up the chimney per hour." A *fireplace* will change the air of an ordinary room in one or two hours.

**Franklin Stoves.**—Franklin stoves consist of coal fires in a cast-iron stove, the products of combustion being carried off through a stove-pipe. Such stoves, standing free in the room, are very efficient, so far as heating is concerned, and also favor ventilation through the circulation of air, which is drawn into the stove to support the burning of the fuel. The heating of the room is unequal, as it depends largely upon radiation and somewhat upon convection. Such stoves are apt to become red-hot, in which case it is believed they allow carbon monoxid to pass through the cast iron. The organic dust in the air falling upon the hot stove is burned and produces an unpleasant smell.

**Open Gas and Oil Heaters.**—Open gas and oil heaters without flues to carry off the products of combustion are objectionable, from a sanitary standpoint. These heaters consist of a variety of designs. The heat is imparted to the room by convection and also by radiation. Such devices may contaminate the air with carbon monoxid from leakage or from unconsumed gas, or from the formation of soot, which becomes incandescent. Such heaters also contaminate the room with  $\text{CO}_2$  and other products of combustion. The "rubber" tube feeding these gas heaters often leaks, and there is frequently a perceptible odor of gas in rooms where these devices are used. Open heaters burning oil are less objectionable than those using gas.

**Hot-air Furnaces.**—A hot-air furnace consists of a coal fire which heats a series of tubes or plates in the dome of the furnace. The air, which is usually taken from the outside through a duct, flows into this dome, where it comes in contact with very hot surfaces, and is thus conducted by thermal circulation through a series of ducts into the rooms of the house. A hot-air furnace of this kind constantly pumps fresh air into the house and is, therefore, a very efficient system of ventilation. The objection to the hot-air furnace is that the air is excessively dry and often partly "burned" in passing over the heated surfaces in the dome. The odor caused by the burning of the organic particles in the air may frequently be noticed in houses heated with a

hot-air furnace. The heated air entering the rooms is usually allowed to escape as it will. In order to overcome the disadvantage of the dryness of the air furnished by the hot-air furnace, water pans are always provided, from which the water is supposed to evaporate. These pans are ridiculously small and cannot possibly furnish sufficient moisture for the great volume of air constantly passing through one of these furnaces. For instance, according to Harrington, air at  $25^{\circ}$  F. saturated with moisture and then heated to  $70^{\circ}$  F. would need half a pint in every thousand cubic feet to give it a humidity to 65 per cent. Ingersoll calculates that a house containing 17,000 cu. ft. of space would require for a relative humidity of 40 per cent. at  $70^{\circ}$  F. in the air already containing 20 per cent. humidity and changed once an hour, about 15 gallons of water a day. The little water pockets in the average hot air furnace are insignificant and inadequate.

The air from a hot-air furnace is drier than that furnished by any other system of heating or ventilation. Thus, an out-of-door air in winter at a temperature of  $0^{\circ}$  F., with a relative humidity of 50 per cent., when heated to  $70^{\circ}$  F., will have a relative humidity of only 3 per cent. This is drier than the air of the driest climate known, which is seldom less than 30 per cent. The average relative humidity in Death Valley, Calif., is 23 per cent.; at Yuma, Arizona, it is 35 per cent. during the driest month of the year; at Santa Fe, New Mexico, it is 29 per cent.; and at Pueblo, Colorado, it is 38 per cent. It is not unusual for the excessively dry air of a furnace-heated house to cause the woodwork to shrink and fall apart, the bindings of books to crack, etc. Living in such an atmosphere is not normal and must be harmful (page 912).

**Hot-water and Steam Pipes.**—This is a very simple and effective system of heating buildings. The hot-water system is especially applicable to small buildings and steam pipes to large buildings. The hot water is more readily controllable than steam, which has a tendency to overheat. Special furnaces are found on the market to heat the water or to generate the steam, which then circulates through pipes to the rooms where wanted. If the hot-water radiators or steam coils are exposed directly in the room, the system is known as the "direct." In the indirect system the hot-water pipes or steam coils are placed in a special box where the air from the outside is heated, and this heated air flows by thermal circulation through ducts into the rooms where wanted. The best practice uses a combination, namely, the direct-indirect system. In the direct system the air of the room is simply heated and reheated over again, while in the direct-indirect system the fresh warmed air is constantly pumped into the building and it is, therefore, an efficient method of ventilation. In both these systems the air is abnormally dried, just as it is in the hot-air furnace, though

not to the same degree. Actual tests during the winter time of the air of a steamheated office in a modern building at Topeka, Kansas, showed the average indoor relative humidity to be 23 per cent., with an average temperature of 72° F. The outdoor humidity at the same time averaged 82 per cent.

**Electric Heating.**—Electric heating is clean, easily regulated, but expensive. It has the disadvantage of being insufficient as a ventilating device, unless special inlets and outlets are provided. Electric heaters consist simply of resistance coils which heat the room mainly through radiation and convection.

**The Cooling of Rooms.**—Much attention has been given, through necessity, to the heating of rooms in winter time, but heretofore little attention has been given to the cooling of rooms in the hot season. It is quite as practicable to cool rooms as it is to heat them, and sometimes quite as important to health.

The principle of practically all cooling devices depends upon the fact that when a fluid evaporates to its gaseous state it absorbs a considerable amount of heat—latent heat. This heat is taken from the surrounding objects which, therefore, become correspondingly cold. Cold may also be produced by the expansion of air. This was pointed out in 1845 by Joulé. Thus, if a jet of air at 60° F. were blown into a room under pressure of 10 inches of mercury above the ordinary barometric pressure, the sudden expansion of this compressed air would reduce it to a theoretical temperature of 13.3° F. below freezing. This principle of dynamic cooling has been applied to refrigerators.

Ammonia gas is now almost universally employed in freezing machines. This gas is readily condensed into a liquid. The compressed gas is allowed to expand into tubes, and the cold thus produced utilized directly; more frequently an indirect method is used by which the expanding gas first cools a freezing mixture consisting of a saturated solution of calcium chlorid; this chilled brine is then pumped through a series of pipes to the refrigerator or apartment where it is desired. Humidifiers and air washers are also used to cool rooms and buildings.

A simple method of cooling a room is by the rapid evaporation of water. Dr. Manning was able satisfactorily to cool a large room in the Government Printing Office at Washington by blowing air by means of an electric fan over a moist sheet. This sheet, about a yard wide, was hung near the ceiling, and constantly wetted by a stream of water flowing over it.

The Mt. Sinai Hospital in New York provides a specially cooled room for babies with summer complaint, in view of the direct relation between heat and infant mortality.

## SECTION VII

### SOIL

#### CHAPTER I

##### GENERAL CONSIDERATIONS

The upper layer of the earth's crust, known as the soil, is derived from the disintegration of rocks and the decay of animal and vegetable matter of all kinds. It varies from a few inches in depth to several feet. The sub-soil also varies from a few feet to hundreds of feet in depth, to hard pan or an impermeable stratum.

From a sanitary standpoint the soil must be regarded as our friend rather than our enemy. Enormous quantities of organic matter and infections of all kinds find their final resting place in the soil and are there disposed of and rendered harmless by nature's beneficent processes. In fact, a closer study of the functions of the superficial layer of the soil shows that it is not only the organ of digestion and respiration of the earth, but, like the liver, it is the great organ in which toxic substances of all kinds are neutralized or destroyed.

The sanitarian does not look upon the soil as dead and inert, but rather as a living being, for it presents many of the vital phenomena that characterize life: digestion, metabolism, assimilation, growth, respiration, motion, and even reproduction. The soil breathes, it absorbs oxygen and exhales carbon dioxid; it is capable of digesting and assimilating vast amounts of organic matter by a complex process of metabolism; the waste products are excreted. If these wastes are retained the soil may be choked or killed by an accumulation of its own poison—a sort of auto-intoxication. The soil, like all living things, demands water, but it may be drowned by an excess. A water-logged soil dies in very much the same sense that an individual dies who has suppression of urine. Sedgwick speaks of the "living earth" in the sense that it is teeming with life; bacteria, molds, amebae, and many of the primitive forms of the animal kingdom, as well as worms, insects, snakes, birds, rodents, and many other animals, make their temporary or permanent homes in the upper layers of the earth. Earthworms by their plowing action, so beautifully shown by Darwin in 1881, constantly turn over the upper layers of the earth. The soil, therefore, is in con-

stant peristalsis, which helps its digestive functions. The rise and fall of the ground water is analogous to the movements of the diaphragm and assists the respiratory functions of the soil.

**Classification of Soils.**—Soils are variously classified, depending upon the amount of sand, gravel, clay, loam, humus, peat, muck, rock, alkali, etc., which they contain. The difference between a sandy and gravelly soil depends mainly upon the size of the particles. These soils interest the sanitarians because hookworms live and flourish in them better than they do upon clay or rock formation.

Clay exists in particles of the smallest possible size. It is very cohesive, possesses a high degree of plasticity, and plays a very important part in determining the fertility of soils, their texture, and their capacity for holding water. Its plasticity is due to the presence of a small proportion of hydrated silicate, and is modified very greatly by the addition of less than a hundredth part of caustic lime. It is exceedingly impermeable to water, and when wet dries with great slowness. Clay may be regarded as a plastic colloid, but its special properties are only seen when a certain amount of water is present. The separate particles of clay are so small that, when placed in water, they assume a state of Brownian movement and sink only very slowly in spite of their high specific gravity. Traces of electrolytes have a profound effect on these properties; small quantities of acids or salts cause the temporary loss of plasticity, impermeability, and the property of remaining long suspended in water without settling; the clay is now said to be flocculated. The change can be watched if a small quantity of any flocculating substance is added to the turbid liquid obtained by shaking clay with water; the minute particles are then seen to unite with larger aggregates which settle, leaving the liquid clear. There is, however, no permanent change; deflocculation takes place and the original properties return as soon as the flocculating agent is washed away. Alkalies (caustic soda, caustic potash, ammonia, and their carbonates) deflocculate clay, causing it to remain suspended in water for long periods. Clay is thus an electro-negative colloid, its reaction probably being conditioned by a trace of potash liberated by hydrolysis. It shows the general properties of electro-negative colloids as elucidated by Schultz and by Hardy; thus, it is flocculated only by a solution containing ions or particles of opposite electrical sign, and the extent of flocculation increases rapidly with the valency and concentration of the ion.

Loam consists of a mixture of sand, clay, and humus. If the sand predominates the soil is said to be light; if the clay predominates, heavy. A rich soil contains an abundance of humus.

By humus is meant the products of vegetable decomposition in their various intermediate stages of decay. It is the essential element of

vegetable mold, and is necessarily of most complex composition. It is composed of a great number of closely related definite chemical compounds.<sup>1</sup> Humus contains a high percentage of nitrogen, especially marked in some of our prairie soils and in the "black soil" found in the provinces of the Ural Mountains, which, according to von Hensen, contains as much as from 5 to 12 per cent. of organic matter.

**Surface Configuration.**—Geodesy, or surface configuration, has an important relation to health. Low and swampy ground is a breeding place for the malarial mosquito. Highlands are apt to be drier and more healthful than lowlands. A slope affords better drainage than flat lands, and thus diminishes the dangers from soil pollution, but increases the risk of infection being washed down from those living above. In narrow valleys the air stagnates, the moisture is excessive in both the soil and the air, and there is an unpleasant blanket of cold layers of air at night. Mountain sides are notoriously windy. High plateaux suffer from extremes of temperature. Thus, at Mexico City (about 8,000 feet above sea level) there is a sharp contrast between the temperature during the day and night, and even during the daytime between the sunshine and the shade. At Quito, which is 9,350 feet above the sea level, the daily variation of temperature at some periods of the year is no less than 34° F. Northern exposures do not get enough sunshine, and southern exposures sometimes too much.

The relation of the surface configuration of the land to health is intimately interwoven with the whole question of climate, and must take into consideration temperature, air movements, humidity, sunshine, barometric pressure, precipitation, and the seasons with their endless varieties from tropical to arctic.

**Composition of the Soil.**—Much attention was formerly given to the hygienic importance of the chemical constituents of the soil. The presence of organic substances was regarded not only with suspicion, but even as a serious menace to health. It was claimed that organic pollution of the soil made a good culture medium for the germs of infectious diseases. The gaseous products of decomposing organic matter in the soil have long been looked upon as particularly injurious. These gases, with other ill-defined but unknown volatile substances, are spoken of as miasma or effluvia.

We now know that very few, if any, of the bacteria pathogenic for man grow and multiply in the soil under natural conditions. The spores of tetanus, malignant edema, and anthrax may live in garden earth for many years, but it is doubtful whether these microorganisms, especially the anaërobcs, ever find conditions favorable for growth and multiplication in the soil. Ordinarily typhoid, dysentery, and cholera bacilli do not flourish in the soil; on the contrary, they soon die there. It has

<sup>1</sup> See Bulletins of the Bureau of Soils, Dept. of Agriculture.

been shown that cities built upon polluted soils have sometimes suffered relatively less from typhoid and cholera than cities built upon rocky or virgin soil. In some cities (as Budapest) it has been pointed out that the greatest morbidity and mortality rate was in that part of the city built upon made ground filled in with trash and much organic waste. These instances have been largely coincidences, for, as a rule, the low-lying, polluted soil happened to be the poor, crowded tenement district. A sanitarian does not recommend polluted soils for building sites, but it seems that their influence upon health has been overstated, especially where cellars are properly constructed. While a polluted soil may not be hazardous in the ways just indicated, it may be dangerous so far as hookworms and other parasites are concerned, or indirectly it may lead to contamination of drinking water, food, etc. See *Pollution of the Soil*, page 1004.

*Mineral Matters in the Soil.*—By far the most abundant element in the soil is oxygen. According to various estimates, from 33 to 50 per cent. of the solid crust of the earth consists of oxygen. The other elements found in abundance in the soil are: silicon, carbon, sulphur, hydrogen, chlorine, phosphorus, fluorine, aluminium, calcium, magnesium, potassium, sodium, iron, manganese, and barium. Aluminium silicate or clay makes up perhaps two-thirds of the inorganic components of soils. Other compounds are lime and magnesia carbonates (limestone) and numerous chlorides, sulphates, phosphates, oxides, etc., of the various bases.

Iron is universally present and gives the red color to soils. Nitrogen exists in soils in three distinct forms: (1) protein and its split products, (2) ammonia and its salts, and (3) nitric acid and nitrates or nitrous acids and nitrites.

*Vegetable Matter in the Soil.*—The vegetable matter exists in the soil in various stages of decomposition. One result of the decay of vegetable substances is the formation of organic acids, which have considerable power to dissolve mineral substances, accounting in part for the plumbisolvant action of acid-reacting surface waters from swampy lands.

Peat or muck results from the incomplete decay of vegetable matter under water.

*Animal Matter in the Soil.*—Organic matter of animal origin in soils results chiefly from the decomposition of carcasses or from contamination with the excreta of animals. As a rule, animal matter is neither so abundant nor so widely distributed in the soil as vegetable matter. From a sanitary standpoint soils polluted with organic matter of animal origin present a greater danger than soils polluted with vegetable matter.

**Physical Properties.**—In general it may be said that the physical properties of a soil are more important, from the standpoint of health,

than its chemical composition. It is a spongy mass, radio-active and contains numerous colloidal bodies.

*Porosity.*—By the porosity, or pore volume, of a soil is meant the volume of the interstices between the particles, which may be filled with water or air, or both; in other words, the power to absorb water. Porosity is expressed as a percentage of the whole mass. Ordinarily the pore volume in soil amounts to about forty per cent.; some apparently compact masses, such as sandstone, have as much as thirty per cent. The pore volume of the soil is independent of the size of the individual grains.

*Permeability.*—The permeability of a soil is its ability to allow the passage of water; it does not depend upon the pore volume, but upon the size of the individual pores. Rocks may have a high porosity, but slight permeability, due to the extreme fineness of the pores. Clay has a high porosity, but its permeability is slight, owing to the extremely small size of the pores, although their aggregate capacity is rather large. The presence of fissures and joints in the rock will greatly increase its transmitting power.

*Water Capacity.*—The water capacity of the soil is the amount of water held in the interstices of the soil when saturated, while the *water-retaining capacity* is the amount of water held back after a saturated soil is drained.

*Soil Temperature.*—The sun is the principal source of the soil temperature. Some heat is produced from chemical changes, but not in considerable amounts. The original heat of the earth's interior furnishes a constant source of heat that is of much importance.

The heat absorbed and given off by the soil has a notable influence upon the atmospheric temperature. Some soils and moist surfaces absorb heat from the sun and give it off again when the sun has set. The most heat-absorbent soils are sandy soils. The sand of the desert may be heated to 200° F., and when this hot sand is raised by simoons the temperature of the air in the shade may reach 125° F. or more. The power of absorbing or reflecting solar heat also depends upon the color of the soil.

*Adsorption.*—The soil has, to a remarkable extent, the property of adsorbing odors and gases, and ordinarily it is very hygroscopic. The soil is also capable of holding toxins, colors, and other substances through the physico-chemical property of adsorption. In this respect it acts like charcoal. Illuminating gas from leaky mains may be divested of its odorous constituents in its passage through the soil, so that its presence in houses may be undetected, thereby greatly increasing the danger. In the experiments made by Abba, Orlandi, and Rondelli about the filtering galleries of the Turin water supply the property of the soil to hold back substances in solution was shown. Cultures of

*Bacillus prodigiosus* in large volumes of water poured into the ground at various points made their appearance 200 meters away in 42 hours, whereas dyes, such as methyleosin and uranin, could not be detected until after 75 hours.

**Soil Air.**—Air is present in all soils, even in the hardest rocks. Sandstone may contain from 20 to 40 per cent., sand from 40 to 50 per cent., and humus as much as 2 to 10 times its own bulk. The soil air differs markedly in composition from that of the atmosphere. It is usually very moist and contains various gases, especially carbon dioxid, resulting from the decomposition of organic matter. For the same reason soil air contains less oxygen than the free atmosphere. The soil air varies greatly, according to the character of the soil, the climate, the season, and rainfall. There is a continual interchange between the air of the soil and the air of the atmosphere. This interchange is influenced by differences in temperature, by rainfall, and by the movements of the ground water and by barometric pressure. Rain chokes the pores and checks soil ventilation. The soil air is in constant motion.

Following the teachings of Pettenkofer, the amount of carbon dioxid in the soil air was for years taken as an index of the amount of soil pollution. It is now well known, however, that this is not a reliable index, for the reason that many conditions influence the amount of  $\text{CO}_2$  in soil air. A soil recently manured may contain from 2 to 5 or even 10 parts of  $\text{CO}_2$  per thousand. In a gravelly soil the proportion may be as high as 80 parts per thousand.

Soil air may influence health when contaminated with poisonous gases, such as carbon monoxid. This occasionally happens. In the open these gases would be so greatly diluted that they could scarcely exert a deleterious influence, but when concentrated, as they sometimes are in dwellings, and breathed for a long period of time they may be responsible for anemia, headache, and other symptoms. Soil air containing carbon monoxid may be sucked into a dwelling from long distances in a lateral direction. Leaky gas pipes may thus render the air of a dwelling impure if the cellar is permeable. This is favored by the pumping action of the furnace, especially when the surface of the ground is frozen.

Soil air is practically sterile; that is, under ordinary conditions it contains few bacteria. Odors sometimes contained in the air from a polluted soil have no known injurious effect.

**Soil Water.**—The passage of water through the soil is essential to soil activity. The moisture favors the bacterial growth by which soils purify themselves and favors vegetation. Nitrates, chlorids, and other soluble substances are dissolved in the water and pass into the subsoil, or furnish food to the roots of plants. A soil absolutely dry, as

a desert soil, is lifeless. A soil with an excess of moisture, that is, one in which the ground water level is at or near the surface, delays and alters the natural decomposition of organic matter. In the deeper layers of the soil, where no bacterial action takes place, vegetable matter may remain almost permanently without change. Thus, wooden piles are not attacked after centuries.

Water exists in the soil in two principal forms: (1) *soil moisture*, which comprises the water present in the interstices of the upper partly saturated layer, as well as the watery vapor contained in the soil air; and (2) *ground water*, or subsoil water, in which case the interstices of the soil are completely filled.

The soil moisture is estimated by determining the loss of weight by drying 10 grams of soil at 100° C. to constant weight. The dry sample may then be exposed to air saturated with moisture under a bell jar and again weighed. The increase in weight indicates the absorptive power of the soil.

Water may also be regarded as existing in the soil under three conditions, viz., hygroscopic, capillary, and gravitation. The hygroscopic water is that which adheres to the surface of the soil particles in the presence of air. The capillary moisture is that which is held within the spaces that are capillary in their nature. The gravitation water is that which drains through the soil and accumulates in the subsoil over an impermeable stratum. For a discussion of ground water see chapter on Water.

It is generally stated that a persistently low ground water level, viz., 15 to 20 feet, is healthful, and that a persistently high ground water level, viz., 3 to 5 feet, is unhealthful, and that a ground water level that fluctuates suddenly is still more unhealthful. Pettenkofer found that typhoid fever was more likely to occur at Munich, Berlin, and Leipzig when the ground water level was at its lowest. His explanations to account for this were ingenious, but we now know that the relation was only a coincidence, for the same does not hold in other places.

Subsoil drainage is usually considered more of an agricultural necessity than a public health question. Large tracts of our land in the Middle West and in other parts of the world have normally a high ground water level, and it is necessary to bring this down in order to increase the fertility of the soil. This is done by draining the subsoil, which also abolishes marshy and swampy lands, and thus puts a check upon malaria.

One of the principal influences of the soil upon general health is through soil moisture. Dampness in or near the surface of the soil may affect the health of those dwelling nearby. Such a soil is cold, and the atmosphere immediately above it is liable to be damp, and this

appears to conduce to rheumatism, neuralgia, and diseases of the respiratory tract. Investigations seem to indicate that the general health of those dwelling on damp soils is inferior to that of those more favorably circumstanced in that regard.

**The Nitrogen Cycle.**—The most interesting of the vital phenomena taking place in the soil is the disposal and utilization of organic matter. This may best be illustrated by the nitrogen cycle, which must be understood in order to have a clear conception of soil pollution, water purification, and sewage disposal.

The nitrogen cycle is a complex series of events which protein matter undergoes, in which it is reduced to simple and stable inorganic compounds, and then returns through plant life to the animal kingdom. One phase of the cycle, namely, the breaking down of animal and vegetable matter, is due almost entirely to bacterial action. The other phase, namely, the building up of complex living organic matter from simpler compounds and elements, is mainly a function of living plants.

The nitrogen cycle is a process in which the anabolism or synthesis occurs in plants, while the catabolism or analysis is brought about chiefly through bacterial action. Hence the series of events constituting the nitrogen cycle largely depends upon the plant kingdom. The important phases of the cycle occur upon the soil and in its superficial layer. It will presently be seen that this cycle has a fundamental importance in sanitary science, and has a special significance in preventing soil pollution, in the purification of water, and in the disposal of sewage. It is evident that any permanent break in this cycle would result in the cessation of life upon the earth.

As soon as an animal or plant dies its protein constituents are at once attacked by putrefactive bacteria. The proteolytic microorganisms (aided by the larvae of insects) growing in and upon the nitrogenous matter break it up into secondary and simpler products, which have a striking resemblance to the cleavage products of gastric and pancreatic digestion. Some of the putrefactive bacteria, of which the *Bacillus subtilis* and the *Bacillus proteus* are important types, liquefy protein matter during the process of putrefaction. Other bacteria, of which the colon bacillus is a type, break down organic matter without evident liquefaction. Very many other species of bacteria take part in this stage of the cycle. For the most part the microorganisms pathogenic for man are killed during the process of putrefaction; they die in the struggle for existence. The processes of decomposition are essentially the same, whether the organic matter is the carcass of an elephant, a beetle, a tree, or a leaf, provided that the necessary moisture, warmth, and other conditions for bacterial growth are present. The breaking down of vegetable matter is slower and more difficult than the break-

down of animal matter. This is due in part to the fact that the latter contains larger percentages of putrescible protein and also usually contains more moisture, which favors bacterial activity.

The breaking down of the complex protein molecules to simpler and stabler compounds is usually spoken of as mineralization, and may be regarded as a series of oxidations. According to our present chemical conception, it is really a series of hydrolyses. The complicated molecular structure of protein matter is analyzed into amino compounds of simpler and simpler composition, until nitrogen finally ap-

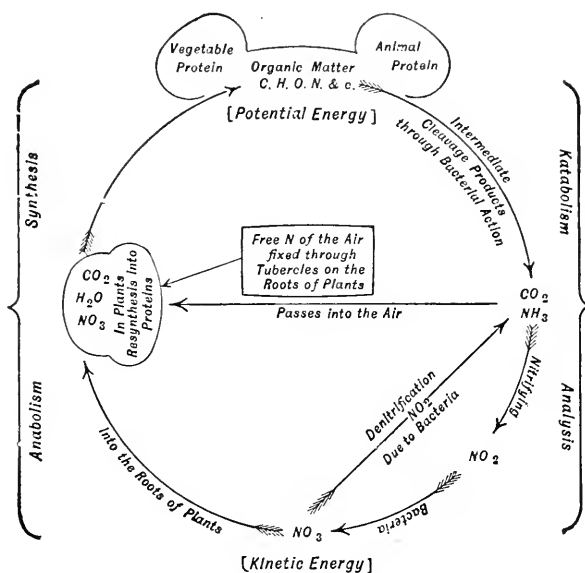

FIG. 103.—THE NITROGEN CYCLE.

pears in the form of ammonia. We know little of the chemistry of the early stages of protein decomposition. The process seems hopelessly complicated from the intricate structure of the molecule. Eventually from the seething caldron of molecular disintegration there appear simpler substances, such as proteoses, peptone, ptomains, amins, leucin, and tyrosin, and other amino substances, as well as organic acids, indol, skatol, phenol, and finally sulphurated hydrogen, mercaptan, carbonic acid, and ammonia. One of the final products of the process is carbon dioxid, part of which passes into the atmosphere and part of which is retained in the soil as carbonates of alkalies or alkaline bases. The ammonia, as such, cannot be used by plants. Some of it may escape into the atmosphere, but for the most part it is retained in the soil as ammonium chlorid or ammonium carbonate. In the soil the ammonia is oxidized by the action of nitrifying bacteria into nitrates. This

nitrifying action of bacteria, elucidated by Winogradsky<sup>2</sup> in 1888, was one of the brilliant discoveries in bacteriology. Through his ingenious work and that of later workers, it is now known that this process is usually accomplished in two distinct steps. The ammonia is changed to carbonate, which is rapidly oxidized by nitromonas into nitrite, and this by nitrobacter into nitrate.

These nitrous or nitrite bacteria were called by Winogradsky nitromonas and nitrococcus. This action is very specific. The ammonia is changed to ammonium carbonate which is rapidly oxidized by nitromonas into nitrite. Nitromonas occur in several forms, mostly oval or

FIG. 104.—THE NITROGEN CYCLE IN DIAGRAMMATIC VERTICAL SECTION.

coccus-shaped; a zoögleal stage is also found. It is spore-free, requires an alkaline medium, aerobic, and widely distributed.

The nitrites exist in the soil probably as salts of potassium and sodium. They remain as the lower oxid a very short time and, therefore, never accumulate, and are never found in any large amount for they are unstable and readily oxidized to nitrates. The special nitric or nitrate bacteria (*nitrobacter*) were first accurately described by Winogradsky. Nitrobacter is also very specific in its action. It is rod-shaped, aerobic, spore-free, requires an alkaline medium, and is widely distributed. No other organism is known with certainty to produce nitrates in soil. The nitrates are stable and represent the final stage of the mineralization of nitrogenous matter. In certain arid parts of the world large deposits of nitrates ( $KNO_3$ , saltpeter) are found as the result of the nitrification of bird excrement (guano), which is

<sup>2</sup> Winogradsky, S.: *Ann. de l'Inst. Pasteur*, 1890, IV, pp. 275 and 760; also *Arch. des Sci. Biol.*, St. Petersburg, 1895, III, 297.

rich in available nitrogen. These collections, however, do not occur in places where there is enough rain to carry away the readily soluble nitrates.

Ordinarily the nitrates go into solution in the ground water and are either taken up by the roots of plants or are washed away in the ground water. In a sanitary analysis of water taken from the soil the presence of nitrates and nitrites, therefore, has a special significance. If nitrites are found in soil water it indicates pollution and signifies active bacterial action and the presence of organic matter. Nitrates in soil water, without nitrites, are an index of past pollution (see Water Analysis).

In 1886 Gayon and Dupetit described two organisms, *B. denitrificans*  $\alpha$  and  $\beta$ , capable of completely reducing nitrates. Many bacteria have this power of denitrification, a sort of reversible process by which nitrates are reduced to nitrites, and then to ammonia, and further to gaseous nitrogen. This is characteristic of very many of the well-known micro-organisms, such as the colon group, pyocyanus, subtilis, and other soil bacteria. Maassen found this action in 85 of 109 kinds of microorganisms studied. Denitrification, however, does not occur in a well-ventilated soil, for it requires lack of air, presence of much decomposable organic matter and of nitrates,—a combination rarely found in nature.

In plant metabolism the nitrates are used to build up new protein. Certain plants get some of their nitrogen through the bacterial tubercles on their roots, which have the power of fixing the free nitrogen of the air. These small nodules are abundant on the roots of various leguminous plants (peas, clover, etc.). Pure cultures of the legume or nitrogen fixing bacteria, such as *Bacillus radicicola* of Beijerinck,<sup>3</sup> may be obtained from these root tubercles. Bacterial inoculation of soils to replace nitrogenous manuring is a fascinating possibility, but has not been realized in practice.

It should be noted also that certain bacteria (azobacter) have the ability to fix the free nitrogen of the air independently of plant life and may grow under either aerobic or anaerobic conditions. One of the first known of this group was an anaerobe described by Winogradsky in 1895 and named by him *Clostridium pastorianus*.

It will be noted that in the nitrogen cycle all the essential steps, from proteolysis to mineralization of the organic matter, nitrification, oxidation, and reduction, as well as the fixation of free nitrogen from the atmosphere, are all the result of bacterial action. Each stage of the complex process is specific, in the sense that it requires a particular species or group of bacteria to effect the result, and also specific in the sense that special conditions of environment are necessary for its action

<sup>3</sup> Beijerinck, *Botan. Ztg.* 1888, xlvii, 725.

Upon special media, colonies of *B. radicicola* yield rods 1 to 5 $\mu$  long, some of which show signs of bacterial formation and "swarmers," so small that they will pass a porcelain filter.

to take place. *Nitromonas* will oxidize ammonium carbonate and nothing else; it will not touch nitrites, urea, or the substituted ammonias. *Nitrobacter* is equally specific.

It is important to remember that practically the entire cycle takes place upon the surface and in the upper layers of the soil. A few feet below the surface of an undisturbed area the soil contains few or no bacteria. Carcasses buried deep, or sewage placed too far below the surface, do not profit by the nitrogen cycle in its entirety, and under such circumstances incomplete nitrification takes place. Nature's method of disposing of dead wastes is thereby defeated, and pollution of the soil and infection of the ground water may result.

**The Carbon Cycle.**—Carbohydrates, such as cellulose, starch, sugars, and similar constituents of vegetable and animal matter, are fermented, with the formation of carbon dioxide, alcohol, and various organic acids. The carbon in carbohydrates passes through a series of changes, which may be regarded as the carbon cycle. The carbon dioxide resulting from fermentation unites with water in the plant life, and under the action of chlorophyll and sunlight is again synthesized to starch and sugars.

The fermentation of the carbohydrates is also due to the action of microorganisms. In a mixture containing both carbohydrates and protein, as a rule, the microorganisms act upon the carbohydrates first. In other words, the putrefaction of protein is delayed or hindered by the presence of fermentable carbohydrates. For this reason sewage containing wastes from breweries always presents difficulties at disposal plants.

*Fats* are also attacked by bacteria, with the consequent production of acids. The hydrocarbons are broken down with more difficulty than either the carbohydrates or protein. An excessive amount of fat in sewage always gives trouble on a filter. For instance, the drainage from a wool-scouring mill containing lanolin and the discharges from slaughter houses and the wastes from creameries, laundries, and cheese factories containing animal fat present special problems in sewage disposal.

The nitrogen cycle, as well as the carbon, sulphur, and phosphorus cycles are all processes of oxidation—at least the terminal products are nitrates, carbonates, sulphates, and phosphates.

## CHAPTER II

### THE SOIL AND ITS RELATION TO DISEASE

**Bacteria in Soil.**—Countless millions of bacteria occur in the upper few inches of the soil. The enormous overgrowth of bacteria in the upper layers of the soil gives it the sticky, moist feeling which rich soils possess. The odor of the soil, such as that which is particularly noticed after a rainstorm, is due in large part to *Cladothrix odorifera* and other organisms which are commonly found in the soil. Few bacteria are found in an undisturbed soil below a depth of 4 to 6 feet. A sand bed used for filtering sewage shows a similar vertical distribution of bacteria. Below six feet the statement is made that the soil is usually sterile. This is not strictly true, but the numbers are much diminished and bacterial activity has practically ceased. As a rule, living bacteria are not obtained from samples of soil obtained 10 to 12 feet below the surface, except in soils with large pores or crevices, or in cases where the bacteria have been carried by burrowing animals. It is exceedingly difficult to determine the number of bacteria in the soil, as so many of them are anaërobes and vast hordes belong to the nitrifying groups, which grow only upon selective media. The soil is also the home of other species, requiring special conditions for growth in artificial culture media.

Of the ordinary bacteria that grow upon the usual laboratory media Houston found an average of 100,000 per gram in an uncultivated sandy soil, 1,500,000 per gram in a garden soil, and 115,000,000 per gram in a sewage soil. Peaty soils have smaller numbers. The actual numbers must be vastly greater, for many microorganisms in the soil do not grow upon the common media. In fact, the soil is the home of the greatest number and variety of bacteria found anywhere. It is the bacteria in the upper layers of the soil that make it resemble a living gland. Each particle of earth is coated with a zoögleal envelope. The sand and mineral particles form the supporting structures, the coating of bacteria corresponds to the glandular epithelium, and the interspaces between the particles are the capillary and lymph channels.

Most of the bacteria in the soil are saprophytes. The microorganisms pathogenic for man do not find conditions favorable for growth and development in the soil. For the most part the temperature is too low; further, they are crowded out by the overgrowth of the saprophytes. Koch has demonstrated that anthrax and other pathogenic bacteria

may be grown in sterile soil, but cannot be grown in unsterilized soil, that is, in living soil. They die in the struggle for existence. Experiments have shown that the soil of graveyards contains no more bacteria than the corresponding soil in the same locality, and is noticeable by the absence of pathogenic microorganisms. The soil often contains the bacteria (or their spores) of certain wound infections, such as malignant edema, anthrax, *B. aërogenes capsulatus*, and tetanus. The relation of the soil to typhoid, cholera, dysentery, hookworm disease, Cochinchina diarrhea, and other infections will be discussed presently.

The function of the bacteria in the soil may best be understood by studying the fate of organic matter polluting the soil and the processes which accomplish its purification. See Nitrogen Cycle, page 998.

**Pollution of the Soil.**—The soil is capable of disposing of great quantities of organic matter. However, if it is overburdened it remains polluted and may endanger health through contamination of the drinking water and in other ways. It is not only the amount but the kind of pollution, and also the manner of its disposal, that plays a very important part. It must first of all be remembered that the purifying action of the soil is largely dependent upon bacteria, and that this action takes place almost solely in the upper layers. If carcasses are buried deeply, or if sewage is allowed to enter the soil at several feet below the surface, the process of purification is long delayed or checked. A leaky cesspool or broken drain which discharges its contents into the soil at a depth of 5 feet or more may seriously pollute the ground water, whereas the same material placed upon or just beneath the surface may be entirely mineralized and all infection destroyed before it reaches the depth of 5 feet. Vegetable matter in a water-logged soil undergoes a partial and unusual decomposition into muck or peat. Trees buried deeply, where bacterial action is practically absent, remain for many hundreds of years practically unchanged. Many factors retard the purifying action of the soil. Among these the temperature and moisture and absence of oxygen predominate.

When organic matter falls upon the soil it is consumed and digested by the hungry earth. Without this property the surface of the earth would long ago have become clogged with vegetable and animal matter. Albuminous substances are dissolved by the action of the proteolytic bacteria, and converted into simpler chemical compounds. The intermediate products of protein putrefaction are exceedingly complex. For our present purposes it is sufficient to know that ultimately the nitrogen is largely converted into ammonia and the carbon into carbon dioxide. The ammonia is then oxidized by the action of nitrifying bacteria to nitrites, and the nitrites again oxidized to nitrates. The nitrates are the final products of the mineralization of organic matter. Most of the nitrates pass into solution and are carried down into the

deeper layers of the soil or subsoil; some of it is taken up through the roots of plants. The carbon dioxid passes off into the air as a gas, remains in the soil moisture in solution, or is converted into carbonates.

Pathogenic bacteria that may be thrown upon the soil in feces or otherwise are usually detained in the upper layers and finally destroyed there. Under ordinary conditions pathogenic microorganisms are caught in the upper layers of the soil, just as they are caught upon the "schmutzdecke" of a slow sand filter. The soil does not act simply as a mechanical trap. The bacteria are detained and destroyed by a combination of physical, chemical, and vital processes taking place in the upper layers of the soil.

All polluted soils are not equally dangerous. Soils polluted with human feces and urine present the greatest hazard to man. The special menace of soils polluted with human excreta is from typhoid bacilli, hookworms, and other infections discharged in the feces or urine. Hookworm infection is usually contracted directly from soils polluted with human feces, and the eradication of hookworm disease depends primarily upon preventing pollution of the soil. The danger in the case of typhoid, dysentery, cholera, and other bacterial infections is usually indirect through infection of drinking water or occasionally through flies or other mechanical means of transference. A soil polluted with typhoid may endanger either the surface water or the ground water, particularly in limestone formations. Pathogenic microorganisms in a polluted soil may also find their way back to man upon vegetables. Tapeworms and other intestinal parasites pass part of their life cycle on or in the soil, and may infect man directly or indirectly in various ways. The question of soil pollution and the particular ways in which it is related to health have been discussed separately under each disease concerned.

**Dirt.**—The soil is often spoken of as dirt. The soil in the field is "earth," but in the parlor or on our hands it becomes dirt; that is, matter out of place. The word "dirt" is from the old Saxon "drit," meaning excrement. Dirt in the ordinary sense becomes a potential danger, especially when containing human excretions or soil bacteria associated with wound infections.

To the sanitarian dirt includes rubbish, manure, and organic wastes of all kinds. It may be the vehicle, but not the source, of infection. It breeds and harbors flies, fleas, lice, rats, mice, and vermin of all sorts that act as intermediate hosts or carriers of infection. While dirt cannot originate typhoid fever or other infections, it favors conditions which encourage the spread of such diseases. Rubbish in vacant lots, in backyards, in alleys, in cellars, garrets, and other places may be taken as an index of the failure to appreciate the modern teachings of hygiene and sanitation. It was once the chief duty, and still an im-

portant one, of the health officer to insist upon cleanliness of premises and surroundings, both in country and city.

**Cleanliness.**—Cleanliness is the heart and soul of sanitation. We are inclined to place it even before godliness, for cleanliness of body, cleanliness of mind and soul, and cleanliness of our surroundings are essential to a full appreciation of the spiritual virtues. Our conception of cleanliness has greatly changed with our advance in knowledge of the kinds of dirt, the degrees of dirtiness, and the nature of these dangers. We can no longer be satisfied with physical or esthetic cleanliness, but must insist upon biological cleanliness. A tetanus spore upon the shining blade of a surgeon's knife makes that instrument filthy, whereas many such spores on the skin of a chicken may be harmless when ingested. We cannot see the infection upon the common drinking cup, upon the roller towel, upon the point of a pencil that has just been moistened with saliva, or in water, milk, or food, although we well know the danger of such invisible "dirt" that these objects may harbor.

It requires a bacteriologist to tell the difference between clean dirt and dirty dirt. We lack a sixth sense, or microscopic eye, to see and distinguish the harmful germs. We, therefore, must practice scrupulous cleanliness and educate the people to the biological meaning of this term. Long experience has taught the lesson that cleanliness offers a protection against disease; that clean surroundings are apt to be free of infection; and that clean food is apt to be safe food.

Cleanliness of person and environment results in the diminution of the number and perhaps the virulence of many pathogenic microorganisms, such as streptococci and staphylococci. Cleanliness of the type that approaches asepsis would prevent much sickness and save many lives through diminishing the risk of infections. Hill believes that the mildness of modern infectious diseases is due to the lessened virulence, smaller stock, and reduced distribution of the streptococci and staphylococci formerly bred in hospitals and in wounds promiscuously. The public health officer should, therefore, campaign for personal and communal asepsis.

Many houses, especially in poorer sections of cities, lack proper facilities for laundry work. Public laundries, such as are provided in many European countries, would materially help in the campaign for general cleanliness.

At one time the theory of the filth diseases reached the dignity of a special name—the pythogenic theory, first propounded by Murchinson in 1858.<sup>1</sup> Typhoid fever was long regarded as the type of a filth

<sup>1</sup>"I shall bring forward what I consider positive proof that this fever (typhoid) is produced by emanations from decaying organic matter; and I would therefore suggest for it the appellation of '*pythogenic fever*!'" "Contributions to the etiology of Continued Fever," p. 219. "Medico-Chirurgical Transactions," London, 1858, Vol. XLI, p. 221.

disease, and, while we are now dropping that term, we should not forget that typhoid fever is really a filthy disease, for each case means that a short circuit has been established between the discharges from one person and the mouth of another.

**The Influence of the Soil upon Health.**—The soil was formerly accused of being one of the largest and most important factors in the spread of the communicable diseases. It was once regarded as the cause, if not the nesting place, of infections of all kinds; tuberculosis, malaria, typhoid fever, plague, yellow fever, cholera, dysentery, and many other diseases were directly associated with the soil. We now know that comparatively few of the microorganisms pathogenic for man live in the soil, and practically none of them grow and multiply there.

The soil contains a number of bacteria that may be serious when introduced into wounds, as tetanus, malignant edema, anthrax, *B. aërogenes capsulatus*; oftentimes organisms belonging to the hemorrhagic septicemic group; sometimes staphylococci and streptococci.

A soil polluted with human excrement presents the possibility of danger of intestinal infections of all kinds. Thus, bacterial infections, such as typhoid, cholera, and dysentery, or protozoal infections, such as amebic dysentery, or the higher worms, such as hookworms, may all more or less be associated with polluted soils.

Soils containing much organic matter and presenting other favorable conditions afford resting and nesting places for a number of insects, such as flies, ticks, etc., which may carry infections.

Vegetables grown in polluted soils may transfer bacteria, protozoa, or the eggs of worms in a mechanical way from the ground to the mouth. This applies particularly to vegetables eaten raw, such as radishes, lettuce, etc.

Practically all the water used for drinking and other purposes has either rested upon the soil or has percolated through it into the ground. The soil materially affects the character of the water. In this way the soil indirectly influences health variously and sometimes seriously. The relation of water to health is a subject in itself, and is discussed in a separate chapter.

The physical conditions of the soil which have special reference to health are those which influence the temperature and moisture of human habitations. Persons working about cold and damp soils are subject to rheumatic, neuralgic, and respiratory affections.

**Diseases Associated with the Soil.**—*Tetanus.*—Spores of the tetanus bacillus commonly occur in the soil of inhabited regions. They have been found not only in the superficial layers, but sometimes at a depth of several feet. The normal habitat and the great reservoir of tetanus are the intestines of the herbivora. It may also be found in the intes-

tinal contents of man and other animals. Certain savages in the New Hebrides used to smear their arrow heads with dirt from crab holes in the swamp, which they knew by experience to be poisonous. We now know that this material contained tetanus spores.

Tetanus increases as we approach the tropics, where puerperal tetanus and tetanus of the newborn are relatively frequent. Tetanus spores are much more abundant in certain localities than others. For example, certain parts of Long Island and New Jersey have become notable for the number of cases of tetanus caused by small wounds.

The tetanus bacillus probably does not grow and multiply in the soil. It cannot there find the necessary anaërobic conditions, temperature, and other factors necessary for multiplication. The resistance of the spores accounts for the persistence of the infection.

The prevention of tetanus has been discussed on page 95.

*Anthrax*.—Like tetanus, anthrax does not grow in the soil under natural conditions. Its persistence is accounted for by its resistant endospore. Anthrax spores have been found in pastures where infected animals have been confined.

The anthrax bacillus requires oxygen in order to sporulate; the spores, therefore, do not form in the blood, and it is very important not to open the carcass of a sheep or cow dead of this disease before it is buried. The classic researches of Pasteur on anthrax should be studied in this connection. Pasteur examined the field where animals dead of anthrax had been buried twelve years previously. He found the specific bacillus in the soil and demonstrated its virulence by inoculations into guinea-pigs. Pasteur thought that the spores were brought to the surface of the soil by earthworms, and proved the possibility of this by sowing virulent cultures in soil and recovering the bacillus from worm casts. It seems, however, in the light of subsequent investigations that the danger from this source is negligible, so that anthrax, with a few exceptions, can hardly be called a soil infection. This is the case at least with man, for there is no instance on record in which human anthrax has been contracted from contact with the soil.

*Malignant Edema*.—The bacillus of malignant edema is found in the superficial layers of the soil. It is very widely distributed. This organism is also found in putrefying substances, in foul water, and in the intestinal tract of various animals. In 1877 Pasteur first recognized an organism belonging to this group by injecting animals with putrefying liquids. He called the organism the *vibron septique*, recognized its anaërobic nature, but did not obtain it in pure culture. Koch and Gaffky in 1881 studied it carefully and renamed it the bacillus of malignant edema. The bacillus has lateral flagella, an oval spore, and is a strict anaërobe. It is very pathogenic for almost all animals, caus-

ing extensive hemorrhagic edema without the production of gas, which distinguishes it from the gas bacillus of Welch. Wound infections with malignant edema occur, especially with deep punctured or lacerated wounds, which favor anaërobic growth. Before the days of antiseptics this complication was frequent, especially during wars.

*Bacillus Perfringens* (also known as Welch's Gas Bacillus and *B. aërogenes capsulatus*).—This organism is a member of a populous and widely distributed species of bacteria, which have in common the ability to ferment sugars with the production of butyric acid. *B. Welchii* is a large rod, gram-positive, and usually grows singly or in pairs. Spore formation is inconstant and occurs only in alkaline media, never in pure cultures in media containing a fermentable sugar or free acid. It causes stormy fermentation of milk; that is, the milk is quickly coagulated and gas formation is so abundant as to break up the curd and even to force parts of it above the cream ring. A rabbit injected intravenously with this organism, killed within two or three minutes and incubated, presents in twenty-four hours a body enormously distended with gas which will burn with a pale blue flame.<sup>2</sup>

This bacillus is found in the intestinal canal of man and animals, in soil and dust which distributes it widely. When introduced in wounds it causes a serious infection with the production of gas. In the present war many wounds contaminated with the soil of the trenches have been complicated with this infection. A serum has been prepared by Bull and Pritchett, which prevents, but does not cure this infection in man.

Many other microorganisms, especially those belonging to the hemorrhagic septicemic group, occur in the soil and occasionally complicate wounds.

*Typhoid Fever*.—There is a widespread belief, even among sanitarians, that this disease is frequently connected with soil pollution. This belief was given scientific confirmation by Pettenkofer, who propounded the theory that the poison, whatever it may be, is introduced into the soil where, under proper condition of organic filth, temperature, moisture, etc., a special fermentation takes place. Pettenkofer believed that the gases or effluvia thus produced rise, and in some way were capable of provoking disease. Pettenkofer's views of typhoid in relation to the height of the ground water have already been mentioned.

Typhoid bacilli frequently find their way upon and into the soil along with human excreta. Multiplication, however, rarely takes place there. As a rule, the typhoid bacillus scarcely lives a month, possibly two or three months, in the soil. When frozen they may live and re-

<sup>2</sup>"Studies in *B. Welchii*, with Special Reference to Classification and to Its Relation to Diarrhea." J. P. Simonds, *Monographs of the Rockefeller Institute*, No. 5, September 27, 1915.

main virulent for several months, as in the case of the Plymouth episode and the New Haven epidemic. While typhoid fever in cities and towns has no evident direct relation to soil pollution, it is possible to conceive an indirect relation in many cases, especially in camps and in rural districts.

There are numerous ways by which typhoid bacilli may be returned from the soil to the mouth of a susceptible person. It is possible, though not likely, for this to occur directly. So far as typhoid is concerned, perhaps the greatest danger from a polluted soil consists in infection of the drinking water. The ways in which this may occur are discussed in the chapter on water. The transfer of typhoid bacilli from the soil to the mouth may also occur mechanically by means of flies, dust, and dirt. Vegetables grown in a polluted soil may carry typhoid bacilli to the very tips of their leaves.

The pollution of soil with human feces is always a danger and should be prevented. The worst offense in this particular occurs in country districts, where the potential danger is greater than in the city.

*Goiter.*—The soil and its underlying rocky strata have long been associated with endemic goiter, in some indirect way, either through chemical constituents or bacterial contamination of drinking water coming in contact with certain geological formations. Goiter is most prevalent in the regions underlaid by the Silurian, Carboniferous, and Permian systems; while those over the eruptive or crystalline rocks of the Archean group, the sediment of Jurassic, Cretaceous, and post tertiary seas, as well as all fresh-water deposits, are comparatively free from the affection.

In some cases goiter does appear in localities over the second group, but in these places the underlying strata are thin and ground water penetrates to lower groups. It is observed also that the influence of the first group is weakened or lost by superimpositions of the fresh-water strata.

Baillarger, in a review of this subject in 1873, concluded that "it had not been shown that goiter prevailed exclusively on any particular soil, but that it seemed to prove that the endemic is extremely common on the dolomite formations and rare on others."

The relation of goiter to the soil is doubtful, except as it may be deficient in iodine, for simple goiter is due to a lack of iodine in the water, food, or both. For discussion on this subject see page 1150.

*Cholera.*—There is every reason to believe that the cholera vibrio dies quickly when deposited upon or in the soil under natural conditions. The cholera vibrio may be transferred from the soil to the mouth in the ways mentioned above in the case of typhoid. Formerly cholera was believed to be associated with polluted soils, but it now appears that the disease is rarely contracted from the soil, and that the physical and

chemical conditions of the ground play little, if any, rôle in the epidemiology of this disease.

*Tuberculosis and Other Diseases.*—In 1862 Dr. H. I. Bowditch formulated the law of soil moisture from studies which seemed to indicate that tuberculosis was more common in Massachusetts over moist soils than dry ones. If there is any connection between tuberculosis and the soil, the relation must be indirect. Exposure to cold and damp depresses vitality and lowers resistance to tuberculosis. It does not necessarily follow that habitations or workshops are cold and damp because the ground on which these houses are built is wet and cold.

The soil was formerly accused of being responsible for plague, malaria, yellow fever, and a long list of other diseases. The importance of the soil with reference to the communicable diseases diminishes with our increase in knowledge. The number of infections directly associated with the ground are very few, and the indirect influences are less than formerly supposed.

Apart from the one real danger, viz., soil pollution with human excrement, the sanitarian is now inclined to belittle the influence of the soil upon health.

Dampness and cold may favor rheumatic and neuralgic conditions, and also predispose to respiratory infections. In this way association with a cold, damp soil may be prejudicial to health. Clay soils are apt to be damp; sand and gravel soils are readily drained and may be kept dry by means of simple devices. Such soils, therefore, make the best building sites for habitations. As a rule, the foundation of a house should be at least two or three feet above the level of the ground water.

The soil greatly influences the character of the water which rests upon it and which passes through it. This will be discussed in the section on water.

*Hookworm Disease.*—Hookworm disease is closely associated with the soil. It may fairly be considered an infection dependent upon soil pollution. It occurs especially in moist sandy soils rather than on clay or rocky soils. This is due to the fact that hookworm eggs, when deposited in fecal matter, soon dry up and die upon hard rocky or clay surfaces, whereas they find favorable conditions for development upon moist sand or loam. Under these conditions the larvae develop as far as the second ecdysis, which have the power of penetrating the skin. See page 153.

*Other Animal Parasites.*—In a somewhat similar sense many of the animal parasites of man are deposited on the soil and reinfect man during one of the stages of their cycle of development. Most of the intestinal parasites of man are deposited on the soil, and, after a varying journey, sometimes through an intermediate host, again find lodg-

ment in man. In the case of *Taenia solium*, for instance, man pollutes the soil with feces containing the eggs. Hogs devour this infection and return the disease to man. Soil pollution likewise results in the infection of cattle with the eggs of another tapeworm of man, *Taenia saginata*. Various parasitic protozoa have resistant stages that may remain in the soil for long periods of time following their introduction by fecal contamination.

*Ascaris lumbricoides* and *Trichuris trichiura*, two worms commonly inhabiting the intestinal tract of man, have very resistant thick shelled eggs that have been kept alive for as long as five years, so that soil once

contaminated with these parasites may continue to serve as a source of infection for considerable periods of time. Several weeks or more, according to conditions of temperature and moisture, are required for the development of the eggs of these parasites to the infective stage

following their passage from the intestines. If fresh eggs of these two worms are ingested, they pass through the intestinal tract without hatching.

The above table <sup>3</sup> (pages 1012, 1013) gives a list of animal parasites having a relation to the soil during some part of their life history, and may, therefore, be more or less associated with soil pollution. It will be noticed that for the most part Protozoa and Nematoda are contracted directly, whereas Trematoda, Cestoda and Acanthocephala are contracted indirectly and through an intermediate host.

<sup>3</sup>This table was prepared by Ch. Wardell Stiles.

## SECTION VIII

### WATER

#### CHAPTER I

##### GENERAL CONSIDERATIONS

"The greatest influence on health is exerted by those things which we most freely and frequently require for our existence, and this is especially true of water and air" (Aristotle).

While water is not technically classed as a food, it is an essential article of diet. In nature water comes in contact with many surfaces and substances and, therefore, is particularly liable to contain impurities, especially as it is the most universal solvent known. Water is also a frequent medium for the transmission of infection.

From the remotest antiquity the highest value has been placed upon an abundant and pure water supply. Centers of population sprang up in ancient times around those points where it was most readily available, and great expenditures of labor and treasure were made to carry it to places where it was not naturally plentiful.<sup>1</sup>

Water is a prime necessity of life—not only as an article of diet, but also for the proper cleanliness of person, clothing, and things.

It is interesting to note that the number of towns in this country before 1800 having a public water supply was only 16, supplying about 2.8 per cent. of the existing population at that time. In 1850 there were only 83 public water works, supplying about 10.6 per cent. of the census population. In 1897 the total number was 3,196, supplying about 41.6 per cent. of the population. Since then the number has greatly increased, but exact information is not available.<sup>2</sup>

##### COMPOSITION

At the close of the eighteenth century water was regarded as an elementary substance. In 1781 Cavendish discovered that, when an

<sup>1</sup>The date of construction of the Appian aqueduct carrying water to Rome is placed at 312 B. C. Eighteen other aqueducts were constructed at various times until 226 A. D. The one commenced by Emperor Chius and completed by Claudius, according to Pliny, cost 350,000,000 sesterces, or about \$12,700,000.

<sup>2</sup>Baker, M. N.: "Manual of American Water Works," 1891 and 1897.

electric spark is passed through a mixture of 2 parts of hydrogen to 1 part of oxygen, these gases combine to form water. Since then water has been made synthetically, and separated analytically into its component constituents by various methods.

The composition of pure water ( $H_2O$ ) is:

	By Volume	By Weight
Oxygen .....	1 part	8 parts
Hydrogen .....	2 parts	1 part

Pure water is a chemical curiosity; it does not exist in nature. All water in nature contains impurities, in solution and in suspension. Some of these impurities are organic and some are inorganic. They consist of various gases, fluids, and solid substances.

### CLASSIFICATION OF WATER

From a sanitary standpoint water is either good or bad. Commonly waters are classified as pure or impure. It is not possible, however; in the present state of our knowledge, to draw a sharp line of distinction. In the classical reports of the Massachusetts State Board of Health waters are spoken of as normal or polluted. A normal water is free from direct or indirect pollution by waste products from human life or industries. The difficulty with this classification is that normal waters may differ widely in color, taste, odor, and composition, and may, therefore, be unfit for household or manufacturing purposes.

Water is considered pure from a sanitary point when it contains no evidences of pollution from the wastes of man or animal, and is considered pure by the engineer when it contains no lime or salt to form boiler scale, or organic matter in sufficient amount to cause foaming.

A practical classification of water is as follows: (1) good, (2) polluted, (3) infected. A good water may be defined as one of good sanitary quality, as determined by physical inspection, bacteriological and chemical analyses, a sanitary survey of the watershed, and, finally, by practical experience. A polluted water is one containing organic waste of either animal or vegetable origin. A polluted<sup>3</sup> water is a suspicious water. An infected water contains the specific microorganisms of human diseases.<sup>4</sup>

In Europe waters are frequently classified as potable or non-potable. Many cities on the Continent have a double water supply with faucets plainly labeled "potable" or "non-potable," the first being suitable for drinking and cooking purposes and personal use, while the second is intended for miscellaneous household and industrial uses.

<sup>3</sup> Sometimes spoken of as contaminated water.

<sup>4</sup> Chemical poisons such as lead are not included in this classification.

According to location, waters are considered under three classes, viz., rain water, surface water, or ground water.

### PROPERTIES OF WATER

Water is a clear, transparent, tasteless, and odorless fluid; colorless in small quantities; pale blue through a deep column. It freezes at  $0^{\circ}$  C. and boils at  $100^{\circ}$  C. under a barometric pressure of 760 mm. It is practically incompressible; has its greatest density at  $4^{\circ}$  C.; is a remarkable solvent. The latent heat of water and other properties that have a sanitary bearing will be considered in the succeeding pages.

Water is the most widely distributed substance. The hardest crystals and the driest rocks contain appreciable quantities; in fact, crystals could not form were it not for the action of water.

Practically all substances yield to water; it is the most universal solvent known. It dissolves gases; in fact, one of the most important constituents of all natural waters is carbonic acid. Carbon dioxide is always present in the air, and all rain waters contain some of it. Still more is taken up by the water as it percolates through ground covered with vegetation. The presence of this gas increases the solvent powers of the water, enabling it especially to dissolve limestone and many other substances.

### THE USES OF WATER IN THE BODY

As a rule, water is not considered a food, for it may be said to have little or no value when estimated as a force producer within the body. Much of the water which is either drunk or ingested as a part of other foods passes through the body unchanged, but some of it is undoubtedly altered or split up into elements which unite with other compounds. The nature of these processes is obscure, and as yet very little understood. Water is entitled to rank as a food because it enters into the structural composition of all foods as well as all the tissues of the body; it is an essential element of diet, even though it cannot of itself build tissue, repair waste, or produce heat or energy.

Water composes about 70 per cent. of the entire body weight, and its importance to the system, therefore, cannot be overrated. The elasticity or pliability of muscles, cartilages, tendons, and even bones is in a great part due to the water which these tissues contain. "The cells of the body are aquatic in their habits." The amount of water required by a healthy man in 24 hours is, on the average, between 1,800 and 2,100 c. c., besides about 600 c. c. taken in as an ingredient of solid foods,<sup>5</sup> thus making a total of 2,400-2,700 c. c. Twenty-eight

<sup>5</sup> Fully five-sixths of the food in an ordinary diet consists of water.

per cent. of the loss of water from the body takes place through the skin, twenty per cent. through the lungs, fifty per cent. through the kidneys, and two per cent. through other secretions and the feces.

The use of water in the body may be summarized as follows: It enters into chemical composition of the tissues; it forms the chief ingredient of all the fluids of the body and maintains their proper degree of dilution, and thus favors metabolism; by moistening various surfaces of the body, such as mucous and serous membranes, it prevents friction; it furnishes in the blood and lymph a fluid medium by which food may be taken to remote parts of the body and the waste material removed, thus promoting rapid tissue changes; it serves as a distributor of body heat; it regulates the body temperature by the physical process of absorption and evaporation.

One of the most universal dietetic faults is neglect to take enough water into the system. Water may be taken with meals, but never to wash down food; in other words, water must not be used to take the place of thorough mastication.

### THE AMOUNT OF WATER USED AND WASTED

From a sanitary standpoint our aim should be to encourage a generous use of water, but to discourage waste. The conservation of pure water and the economic use of a purified water are pressing problems that a growing and expanding country must meet and solve as a matter of self-interest if not of self-preservation.

It is possible to get along with a surprisingly small amount of water. Thresh found that in a number of country places the amount used in cottages did not greatly exceed one gallon per person per day. This is not sufficient for modern requirements of cleanliness and health.

On the other hand, where the supply is abundant and easy of access large quantities of water are heedlessly wasted.

The average amount of water required per capita for domestic purposes is usually stated at about 17 gallons a day. Rankine considers 10 gallons sufficient. Parkes found that the average amount used by a man in the middle class, who may be taken as a fair type of a cleanly man belonging to a fairly clean household, is 12 gallons per day. This includes the amount used in cooking, drinking, ablution, utensil and house washing, and laundry. Davies' estimate of 17 gallons a day is divided as follows.

Drinking, 3 pints; cooking, 5 pints.....	1 gal.
Ablution (including sponge bath, 2½ gals.).....	5 "
Washing (laundry, 3; house, etc., 3).....	6 "
Water closets.....	5 "
	<hr/> 17 "

The actual per capita daily consumption of water in some cities is, in fact, not much above this figure. Thus, Manchester uses 20 gallons and Berlin 22 gallons a day for each individual. Some small English towns, as Saffron Walden (population 6,108), use 11 gallons per capita per day, and Melrose (population 1,300) uses 13 gallons. As a contrast to these low figures most cities in America are furnished with an extravagant quantity—Pittsburgh, 250 gallons per capita daily, Buffalo, 233, Philadelphia, 227, Washington, 218.<sup>6</sup> The small amount of water used by some European cities is not an ideal to strive for under American conditions. The European figures are steadily increasing, even where all water is sold by meter. In towns having a metered supply the per capita consumption varies from 6.6 gallons daily for the lowest class of dwellings, to 59 gallons for the highest class of dwellings.

The following tables give the per capita consumption in some American cities, contrasted with similar figures abroad.

*The quantities of water supplied in a number of American cities*

<sup>6</sup>These figures include industrial uses.

The amount of water expressed by the per capita consumption of a community is very misleading for purposes of comparison. The figures are usually obtained by dividing the total theoretical amount of water pumped, by the population. The result, therefore, does not take into account many factors, for the actual amount of water pumped does not equal the theoretical possibilities; corrections for slip and other factors should be made. The figures also do not take into account the amount of water lost through broken pipes, leaky joints, etc. It is estimated that in some places almost half the water pumped is wasted in this way. According to Whipple, the water lost and unaccounted for with metered supplies amounts to from 15 to 50 gallons per day per capita. Further, there are great discrepancies when contrasting different cities in the amount of water used for business purposes. The amount of water used in trades and manufactures varies enormously. Certain industries, such as mining, tanneries, coal washing, paper mills, breweries, wool scouring, etc., require great quantities. It is estimated that in the iron, coal, and steel regions of Pennsylvania a quantity of water representing the entire flow of the Allegheny River passes through the large steel, iron, and other mills along its bank several times before it reaches the city of Pittsburgh. Therefore, unless the per capita consumption is based upon the amount of water actually measured by meter for domestic purposes, the figures of one city cannot be properly compared with those of another.

**Causes of Water Waste.**—Few persons realize the immense amount of water that is wasted in almost every town. Taking it right through, probably one-half of the water supply of American cities is wantonly wasted. While some of this is unavoidable, the greater part of it could be stopped. There are three principal causes of this waste: (1) leakage from faulty mains and service pipes; (2) waste from defective house fittings; (3) waste resulting from an unmetered or unmeasured service. The first cause includes leaks from faulty mains and service pipes and all other hidden defects where the water escapes unperceived into drains and sewers or into the subsoil. It is possible to check a large part of this waste by the use of instruments known as detectors. With these instruments leaks may be located. The detectors are of two sorts: (1) aquaphones, instruments resembling a large stethoscope, by which a trained ear may locate murmurs; (2) pitometers, instruments which measure the rate of flow in branch lines during the small hours of the night, when practically no water is used. In this way leaks, defective taps, and open stopcocks may be discovered. It requires but a moment's calculation to figure out the great number of gallons wasted by forgetting to close a stopcock. In some cities, such as Washington, in the winter time the water in many houses is allowed to run continuously

from the cold water faucet, in order to prevent freezing.<sup>7</sup> The waste from this cause is enormous, and may be corrected by properly placing the service pipes so as to avoid the danger of freezing.

**Water Meters.**—It has been the universal experience that much water is thoughtlessly wasted where the service is not metered. The only objection to a metered service is the prejudice common to all innovations, but the advantages are soon realized and the saving is very considerable. The introduction of meters in the city of Washington during the past few years has resulted in checking the waste by reducing the total amount of water consumed one-third, making a saving of from 20 to 30 million gallons of water a day without annoyance or inconvenience to any one. This great saving did not all result from the metering alone, but was aided by the use of detectors and an efficient system of inspection, which checked waste from other causes. In Milwaukee, before meters were generally adopted, the water used per tap was 1,781 gallons per day. After the majority of houses were furnished with meters, the amount used per tap was only 644 gallons. Buffalo reduced her water consumption during the war (1918) from over 300 gallons per capita to 260 with a survey that covered only part of the city. Another notable instance of checking waste was furnished by Liverpool, where the average amount supplied daily per head was 33.5 gallons. Deacons' water waste detectors were introduced, and these, together with efficient inspection, reduced the supply to 23 gallons without any restrictions being placed upon the consumers. At Shoreditch, in England (population 87,000), the introduction of waste detectors effected in the course of three years a diminution of waste and undue consumption amounting to 720,000,000 gallons per annum. At Exeter the introduction of waste detectors reduced the amount from 75 to 12 gallons per head per day.

It is estimated by engineers that 45 per cent. of the water supplied to Manhattan and the Bronx is wasted, and that if this waste were checked the new aqueduct from the Catskills, which cost over \$160,000,000, would not have been needed. While it is necessary to allow a liberal supply, there is no sanitary advantage in waste. Good clean water in large quantities is difficult to obtain and expensive. Economy and avoidance of waste are, therefore, essential.

## DUAL WATER SUPPLY

The question of a dual supply of water, one cheap for general purposes and the other high class for personal use, has often engaged the attention of engineers and sanitarians. Ancient Rome had a sort of

<sup>7</sup> In cities where this practice prevails, more water is used in the winter time than in the summer months.

double supply, and Paris and other European cities have it at present. The advantages and disadvantages of the double system are evident. Even where the community served is intelligent and careful, the danger of a double system is very great, and it will probably never be resorted to except through stress of circumstances.

A number of cities have a separate water system under high pressure for fire fighting. Auxiliary water systems are often connected with the drinking water mains, and controlled by means of check valves, bypasses, etc. This arrangement is hazardous and a number of outbreaks of typhoid fever have been traced to faulty valves or failure to close bypasses in such a dual system.

## SOURCES OF WATER

We may begin the circle by considering that all water comes to us from the aqueous vapor condensed in the form of rain or snow. Of this a certain amount returns to the atmosphere by evaporation; the rest collects upon the surface of the earth or soaks into the ground. Some of it flows off in the direction of surface slope to join the ponds, lakes, rivers, or seas, or some of it may penetrate the earth to variable depths. The sources of our water supply may, therefore, be classified as: (1) rain or snow water, (2) surface water, including ponds, lakes, streams, and rivers, and (3) ground water, including springs and wells. This classification is evidently an arbitrary one, used for convenience. There is no sharp line of demarcation between rain, surface, and ground water. Rain water soon becomes surface water, and surface water quickly passes into the ground; the ground water frequently reappears as springs to form streams and lakes and other surface supplies.

Rain water is nominally the purest and may be free from all traces of organic matter, but is liable to irregularity of composition, and in built-up sections it is difficult to collect it so as to be free from contamination and fit for drinking. Surface water from inhabited watersheds is, in its raw condition, never entirely safe for drinking purposes. Ground water obtained from the subsoil of a catchment area, free from sources of pollution, is usually of a satisfactory character. Artesian water, which is ground water obtained from the deeper underlying strata, is often so rich in mineral matters that it is unsatisfactory for most uses. The various sources of pollution, its character, and dangers will be considered in subsequent pages.

## RAIN WATER

Rain water is really "distilled water," that is, it is water that has been vaporized and then condensed. The process of distillation is one

of the best known methods for purifying liquids of all kinds. All the non-volatile substances are left behind; theoretically, therefore, rain water should approach nearer to absolute purity than any other kind of natural water. However, it receives impurities from the moment it condenses, for each droplet of mist is formed about a particle of dust in the air. The rain drop further absorbs gases, and as it drops through the air collects a large amount of the "dirt" floating in the lower portions of the atmosphere. It is a common observation how a shower will wash the air so that it becomes beautifully clear and clean. The impurities collected by the rain before it reaches the surface of the earth, while considerable in amount, are practically negligible from a sanitary standpoint. After rain touches the earth's surface it becomes, to all intents and purposes, a surface water, unless collected with special precautions to avoid contamination. If collected from a clean, impervious surface in the open country, it is the purest of natural waters. The use of rain water for drinking purposes has met with little favor by sanitarians, despite its exceptional purity, because it is so frequently collected and stored in such a careless manner that it is subject to impurities. It is true that rain water is not likely to be infected with sewage, nevertheless some of the dirtiest waters used for domestic purposes come from rain-water tanks. Even casual inspection will often show that rain water collected and stored in the usual way is very far from being pure, though rarely infected.

Because rain water is soft it recommends itself for use in the laundry, and the absence of lime salts renders it desirable for cooking. On the whole, however, it is not considered as practicable as a good ground or surface water for general domestic supply.

The storage of rain water in cisterns is the principal factor in keeping yellow fever alive in endemic foci. The yellow fever mosquito (*Stegomyia calopus*) breeds by preference in artificial containers holding rain water. It was the abolition of such breeding places that has protected Philadelphia, Boston, and many other seaports, now including New Orleans, that formerly fostered the stegomyia and suffered from yellow fever epidemics. See page 295.

Usually it is advisable to filter rain water collected from the roofs of buildings, especially if situated in towns, near dusty roads, etc.

Underground filters for rain water, in order to purify it before it enters the storage tanks, are sometimes provided. These filters are for the most part unsatisfactory. Either the material is so coarse that little purification is effected, or so fine that it speedily becomes clogged and useless. They rarely receive proper attention and, therefore, are apt to become filthy.

**Amount.**—The average annual rainfall on the globe is computed to be 33 inches. The mean annual rainfall for different portions of the

United States has been tabulated by the United States Weather Bureau to average some 30 inches. In New England and the Middle States it amounts to 40 inches. In Assam from 600 to 805 inches have been recorded, while in the Sahara desert, part of Arabia, the desert of Gobi, and portions of Mexico, Chile, and Peru it has seldom been known to rain. Coles-Finch states that it seems to be a fact that the atmosphere of the earth is growing drier. The glaciers are retreating, the Caspian Sea and many other lakes are growing smaller, and the great deserts seem to be extending. Some of the richest countries on earth have seen their fertility decreasing, mainly owing to lessened rainfall, and this is caused, at least in part, by the ruthless destruction of the forests. Ruined forests mean flooded rivers, periodic droughts, eroded soil, and dried-up springs.

The amount of water given by rain can easily be calculated if two points are known—the mass of rainfall and the area of the receiving surface. The amount is determined by a rain gauge and the area of the receiving surface must be measured. Roughly, the amount may be calculated by multiplying the area of the receiving surface in square feet by half the rainfall in inches, the result being in gallons. Here the error is about 4 per cent. Thus, according to Church, one inch of rain on a house roof 20 x 20 feet area would be about 250 gallons. With a rainfall of 40 inches per annum this would amount to 10,000 gallons, or 27 gallons per day.

The total theoretical amount, however, is never available, for the reason that some is lost by evaporation and the first flow should be wasted. Only a very small proportion of water may be collected from a light shower spread over a considerable interval, especially in hot weather, as nearly all is lost by evaporation.

The stations of Prussia allow the following average for evaporation, the amount evaporated in the open fallow field being called 100:

	Evaporated	Retained More than in Open Fallow Field
	Per Cent.	Per Cent.
Under beech growth.....	40.4	59.6

It is this protection against evaporation which gives to the forest its chief value as a guardian of water supply. The forest floor, with its irregularities and its sponge-like qualities, moreover stops the rapid and ruinous draining of the surface, with attendant denuding of the land, and favors slow percolation through the soil and reinforcement of the springs.

The amount of water that can be utilized from the rainfall, draining a catchment area, may be stated as follows: Taking, for example, an average of 46 inches of rainfall each year upon the catchment area, one-half of this is lost by evaporation from the water surfaces, from the surface of the ground, and especially from the leaves of all the plants and trees that grow upon it. The other half, equal to a rainfall of 23 inches, flows off into streams, and sooner or later reaches the lake or impounding reservoir. In wet years the amount that flows off is greater; in dry years it is less than the average; in the winter and spring months the flow is very much greater than at other times.

**Collection and Storage.**—The points of prime importance in the collection and storage of rain water for domestic purposes are: (1) the material and care of the surface upon which it is caught; (2) the separation of the first flow, which contains most of the grossest impurities; (3) the location and construction of the storage cistern.

Storage cisterns for collecting rain water are frequently placed underground. In some places rain water cisterns are built of cypress wood and always above ground. Tanks of wood serve their purpose well, provided they be kept full. If there is great fluctuation in the water line the tank itself falls out of repair. Rain water attacks iron, lead, zinc, and other metals, and when metal cisterns are used the metal should be coated with a good asphaltum paint. This applies also to the delivery pipe. Under no circumstances should lead cisterns or lead service pipes carry rain water used for drinking purposes. It should not be forgotten that cisterns are liable to the grossest kinds of pollution, and they require frequent inspection and cleansing.

Where the overflow pipes from rain water tanks are connected with sewage drains, precautions must be taken to prevent sewage backing up and entering the tank.

**Composition.**—Rain water varies in composition with the purity of the atmosphere through which it has passed. It always contains dissolved gases, an average of 25 c. c. per liter. These gases are mainly nitrogen, oxygen, and carbon dioxid, taken up in proportion to their absorption coefficients, and not in proportion to the amount contained in the atmosphere. The gases contained in rain water consist of about 64 per cent. nitrogen, 34 per cent. oxygen, and 2 per cent. carbon dioxid. In addition ammonia is very commonly present. The amount of total solids varies; throughout England it averages 0.39 part per million. The principal inorganic constituents of rain water are sodium chlorid; nitric acid and nitrates, sulphuric acid and sulphate; a small quantity of nitrogenous organic matter is also present. The sodium chlorid comes mostly from the sea spray lifted into the atmosphere through wind action. The sulphuric acid comes largely from the waste products of burning coal. Rain water is soft on account of the absence

of the alkaline earths, and is almost always acid in reaction. It has a mawkish taste.

**Bacteria.**—Rain water contains a variable number of bacteria and other microorganisms, the number and kind depending upon the germ population of the atmosphere through which the rain passes. Fortunately the various microorganisms floating in the air and carried down mostly by the first shower are not of serious moment, as far as health is concerned. Pathogenic microorganisms in the air are few in number, and these are soon killed by desiccation or the germicidal action of the direct sunlight, to which they are so thoroughly exposed.

Miquel, at the Montsouris Observatory in Paris, found rain water to contain bacteria, pollen, spores of fungi, protococci, etc., especially numerous in the warmer months. In the first showers after a long spell of dry weather over 100,000 such organisms may occur in a pint.

### *SURFACE WATERS*

Surface waters include rivers, creeks, and smaller streams, large and small lakes, ponds, and impounding reservoirs, all resting upon the bosom of the earth in contact with the atmosphere. Surface waters vary greatly in composition, depending largely upon the character of the catchment basin. A water flowing over a rocky soil or through deep layers of sand and gravel is more likely to be free of organic impurities than one that is drained over loam or has stood in swamps.

From the way in which surface waters are exposed they are subject to impurities, and from a sanitary standpoint are frequently dangerous and almost always open to suspicion. Most cities, especially in America, depend upon surface waters for their supply. This is usually taken from rivers, lakes, or impounding reservoirs. It is scarcely possible, in a populous country, to obtain a large quantity of surface water free from pollution with human wastes. Sanitarians have, therefore, more and more come to the conclusion that, while surface waters used for drinking purposes should be guarded against contamination, as far as practicable, they should also be purified before they are used.

**Rivers.**—Streams are the natural sewers of the regions they drain, and, when used as a source of water supply, we have established a direct connection between the alimentary canals of the people living upstream with the mouths of those below. Most of our large rivers flow through more than one state; therefore, the interstate pollution of streams becomes a national problem. In the older countries of Europe, with more centralized power, laws to prevent the pollution of streams are enforced.

In our country the rivers furnish the chief source of water supply for most of our large cities. The succession of cities and the combined

use of the river as a sewer and source of water supply on such rivers as the Merrimac, Hudson, Delaware, Ohio, Missouri, and Mississippi are particularly impressive. When the water of these rivers has been used in its raw or unpurified state much unnecessary sickness has resulted and thousands of lives have been lost.

No stream draining an inhabited region can be considered safe without some method of purification. There are a thousand minor sources of pollution that practically cannot be stopped, even though the sewage flowing into the stream is treated and all reasonable precautions taken in connection with it. It is well known that very few sewage purification works treat all the sewage from the districts which they serve. Thus, there are storm overflows and street wash that cannot pass through sewers, and other sources of pollution.

Looking at the whole matter of streams pollution solely as an economic engineering problem, it is cheaper to purify the water supplies taken from the rivers than to purify the sewage before it is discharged into them. The volume to be handled is less and the cost of purifying water per million gallons is much less than the cost of purifying sewage. Further, in the present state of our knowledge water may be purified more effectively and with greater certainty than sewage. On the other hand, it is perfectly clear to the sanitarian that the future will require both methods, that is, a reasonable protection of our streams against pollution and the purification of the water served to cities.

*Composition.*—The composition of river water varies very much, according to the part of the river whence it is taken. Near its source the water may be comparatively pure, but it soon becomes polluted. The composition is complex, as the water of rivers consists of a mixture of rain water and ground water, to which are added surface impurities. As a rule, river water is softer than ground water, but contains a greater amount of organic matter.

Sudden and great changes in the character of river water are to be expected. Other changes, slow in operation but serious in result, come from the increasing pollution with sewage from a growing population upon the upper regions of the watershed.

Rivers are generally purer near their source. The amount of impurities increases as we descend the stream, since the water courses are the natural drainage channels of the country, and the wastes of human life and occupation as well as the scourings of the land find their way into the streams. It is for this reason that rivers, after passing through cultivated valleys with cities, towns, or settlements along their banks, often contain a very great amount of mineral and organic matter. Thus, the Mississippi at Minneapolis contains only 18.6 parts of total solids per 100,000, while the same river at St. Louis contains 244.3 per 100,000.

The amount of mineral matter picked up by a stream depends largely on the geological formation of the country and the erosive power of the stream.

Frequent attempts have been made to correlate the flow of streams and the stages of the river with the outbreaks of disease, especially typhoid fever. It is to be remembered that the flow of streams is dependent in most cases not only on the rainfall, but on springs of local origin. Typhoid may be, and usually is, independent of the stage of the river. Outbreaks are often connected with sudden freshets following a long dry spell, and the explanation seems to be that the accumulated filth is thereby washed down from the slopes and banks of the stream. When streams are very low the flow becomes sluggish, sedimentation and other factors influencing self-purification take place in comparatively short distances; when the river is high the rapid flow is more apt to bring fresh and virulent infection. The decline of typhoid fever in Allegheny in 1908 and 1909 was coincident with an exceptionally low stage of the river. During the spring and fall freshets, when the water is cold and the current swift, the danger is the greatest. In other words, it is the rapidity of flow or the time consumed rather than the stage of the river or the dilution, that is most often responsible for typhoid and other infections in river waters.

If typhoid bacilli are discharged into a stream which flows at a rate of 5 miles an hour, which is a comparatively quiet stream, and accepting the usual figures that the bacteria may die in 5 days, these organisms could be carried 600 miles, usually far enough to reach some domestic supply. Hence, any pollution is apt to reach some consumer unless it occurs near the sea. Nevertheless, the Potomac River at Washington seems to be responsible for little or none of the typhoid fever in that city, although it drains an area of about 11,400 square miles, having a population in 1900 of about half a million and receiving directly the sewage of some 45,000 persons. The question of the self-purification of streams is considered on page 1109.

**Lakes and Ponds.**—Fresh water lakes and ponds make admirable sources of water supply when kept free from pollution with the wastes of human life and industry. This is much more practical than in the case of rivers, on account of the limited area of the catchment basin directly draining into a small lake or pond. Lake water is apt to be soft and free from serious organic impurities. In large lakes the dilution of accidental contamination is enormous, and the effects of time, storage, sedimentation, and other purifying factors have a good chance of exerting their maximum influence. The problem from a sanitary standpoint is quite different when we consider large bodies of fresh water, such as our Great Lakes, or smaller lakes and ponds.

*The Great Lakes.*—The lake cities suffer most from the mingling of their own sewage with their own water supplies. This is avoided in part by building the intakes farther out into the lake or by placing the intakes in deep water at points where there seem to be fairly definite currents, bringing fresh, clear water from the body of the lake to the intake. The currents are never constant, being controlled by the wind, hence safety cannot be secured in this way. Almost every lake city has at one time or another suffered from outbreaks of typhoid fever. Chicago has cut a drainage canal to keep her sewage from entering the lake, so that it now flows through tributaries to the Mississippi River. This sanitary reform cost the city of Chicago upward of \$40,000,000, and it eliminates the sewage of a large part of the city, but not including certain areas of Evanston and the north side. Despite this commendable piece of sanitary engineering designed to keep the water clean, Chicago disinfects its water supply with bleaching powder.

Hazen points out that in the smaller cities upon the lakes the mingling of the sewage and water may be relatively just as important as in the larger ones. They have less money to spend, their intakes do not go out so far, their sewers are apt to discharge at the nearest point, sometimes directly in front of the waterworks intake. The water may be shallow and stirred by the wind to the bottom, and, in short, "Menominee's sewage in Menominee's water may be just as bad as Chicago sewage in Chicago water."

The Great Lakes are so large and the dilution and time intervals and exposure to sun and air are so great that there is practically no chance of infection being carried from one of the great cities to another. Thus, Chicago sewage would scarcely endanger the purity of Detroit's water supply, even with no drainage canal. The little city of St. Clair, with 2,543 inhabitants, only 45 miles away, is far more dangerous to Detroit. In the same way Detroit's sewage is probably harmless at Cleveland, and Cleveland sewage is harmless at Buffalo. The sewage of Buffalo, however, is a great menace to those drinking the water at Niagara Falls.

Pollution may travel a variable distance in large lakes. At the mouth of the Detroit River, for instance, serious pollution was shown, extending normally more than 10 miles into the lake, and at other places sewage pollution was shown, extending as far as 18 miles from the shore.<sup>8</sup> The pollution from boats passing near the intake may also be a serious menace.

Most of the cities on our great lakes find it impracticable to extend water pipes into zones of pure water on account of the great cost of these extensions and the engineering difficulties involved in placing intakes beyond a 70 ft. depth. Therefore, in most instances, our lake cities cannot obtain a safe water supply without purification.

<sup>8</sup> Internat. Joint Commission of the U. S. and Canada.

**Impounding Reservoirs.**—Impounding reservoirs are artificial ponds or lakes, usually made by throwing a dam across a narrow valley. Most impounding reservoirs are made along the course of a small stream.

The principal use of impounding reservoirs is to hold the excess of water of the winter and spring flows and make it available during the summer and fall.

The impounding reservoir designed to furnish New York City with a new supply of water to supplement the Croton system is the largest artificial reservoir for water supply in America, if not in the world. It is situated in the Catskill mountains, and is made by damming Esopus Creek, and holds one hundred and twenty billion gallons of water. Boston is supplied from impounding reservoirs on small streams; the Cochituate (1848), the Sudbury (1878), and the Nashua (1898). The Wachusett reservoir stores the combined water from the smaller sources of supply, and has a capacity of 63,000,000,000 gallons of water. Baltimore has an impounding reservoir upon the Gunpowder River; other cities similarly supplied are Newark and Jersey City in New Jersey; Worcester, Cambridge, and Springfield in Massachusetts; New Haven and Hartford in Connecticut; Altoona in Pennsylvania, and Denver in Colorado; San Francisco and Oakland in California; and numerous other smaller cities. From a sanitary standpoint the great advantage of an impounding reservoir is that it drains a comparatively small area that is amenable to control; often the catchment area is in uninhabited hilly or mountainous districts. The other sanitary advantage lies in the fact that benefit is taken of the great sanitary safeguard of storage. Most pathogenic microorganisms die a natural death during the time that the water is stored in a large impounding reservoir. In Boston it is estimated that the water is stored an average of 30 days before it reaches the consumer. Few non-sporulating bacteria dangerous to man can live that long in water under natural conditions.

The chief disadvantage of impounding reservoirs as storage basins is that they are open to the air and light, and thus favor the growth of algae and other microscopic organisms responsible for objectionable tastes and odors. Further, the stagnation of the water favors the accumulation of the products of decomposition, which is another source of evil smells and vile tastes. The stagnation of water in impounding reservoirs and small lakes and ponds deserves special mention.

*Stagnation of Water in Impounding Reservoirs and Small Lakes.*—Hazen points out that in our climate, when a reservoir or lake is more than 20 to 40 feet deep, the upper part of the water is usually in circulation under the influence of the wind, and the lower part remains stagnant. There is little or no mixing between the surface water and the bottom water, except for two short periods each year, one in the spring and one in the fall. These periods of circulation to the bottom

are known to waterworks men as the spring "overturn" and the fall "overturn."

During the summer weather a stratum of warm water remains at the surface. This layer may be 20 feet in small reservoirs, and 40 feet in great lakes. The temperature of this surface layer may reach 75° or 80° F. or more in midsummer. The wind stirs it up to a certain depth (about 20 to 40 feet), depending upon the depth of the reservoir and the force, direction, etc., of the winds.

The bottom layer is cool and quiet. As the air temperature falls with the approach of winter the surface water cools, until it approaches that of the bottom water. When the difference in temperature between the surface and bottom layers is less, the wind action extends deeper, until, all at once, often when the wind is blowing, vertical currents arise, so that all the water in the reservoir turns over and mixes from top to bottom. The mixing continues for a few weeks, until the temperature of the surface water falls below the point of maximum density, namely, 4° C. Then the colder water commences to accumulate at the top. The top often freezes and entirely shuts out wind action, so that the period of winter stagnation is ever more quiet than the summer period. The spring "overturn" is caused by a reversal of the conditions causing the fall "overturn"; surface water is warmed until it reaches the temperature of the bottom water, when the upward and downward currents take place.

It can readily be seen that this phenomenon has much to do with the quality of the water. Thus, the organic matter upon the bottom of almost all reservoirs decomposes, and in the absence of oxygen produces the vile odors and nasty tastes of putrefaction. These odors and tastes accumulate in the bottom water until the fall "overturn"; then they become mixed with all the water in the reservoir. If the water is drawn from the reservoir near the top, as it usually is, there will be a great change in the quality of the water on the day of the fall "overturn." These fall changes are more intense than those which take place in the spring. The surface water is well charged with oxygen, and, as this falls to the bottom, it oxidizes and neutralizes some of these products of decomposition. Tastes and odors due to this cause may be removed by aërating the water by means of fountains, cascades, falling over a dam, or any other similar means. For a further discussion of this interesting subject see Hazen's "Clean Water and How to Get It."

*Stripping.*—Stripping consists in removing the organic matter of the surface soil, which is to become the bed of a reservoir. The object of stripping is to diminish the amount of putrefaction taking place in the bottom of stagnant water, and also to furnish less food for bacteria and algae. A number of the reservoirs in Massachusetts were first stripped at considerable expense. It has been found that in the

older reservoirs prepared in this way putrefaction has not taken place for some years, although in some cases putrefaction seems not to have been entirely prevented, even at the outset. Stripping does not prevent objectionable growths; it only reduces them somewhat, because many of the organisms do not need or make use of the organic matter of the soil as their food supply. The algae live rather on the mineral matters of the water and the air, and, with the aid of the sunshine, they build up their own organic matter, precisely as the higher plants do growing in soil.

### GROUND WATER

Water which is taken from the ground by means of wells or flowing naturally from the ground, as in springs, is usually satisfactory, as far as injurious impurities are concerned. The surface water is greatly purified as it percolates through fine, sandy soil. This is nature's process of filtration; the organic matter is oxidized, the bacteria are largely

FIG. 105.—GROUND WATER.

A, High level. B, Low level. C, Intermittent spring.

strained out. The soil can take care of a large amount of pollution, and, if not overburdened, or if it has no cracks or crevices, the ground water may be entirely free of objectionable organic substances and bacteria. In passing through the soil the water takes up a rather large amount of carbon dioxide, which is set free by organic decomposition. The water, thus acidulated, has a greater solvent action for lime and other mineral constituents, so that ground water is apt to be harder than surface waters, and to contain a larger amount of dissolved inorganic substances. In deeper waters the solvent action is favored by increased heat and pressure, so that deep wells and artesian waters are frequently unfit for domestic use on account of the large amount of inorganic impurities which they contain, such as lime, iron, common salt, etc.

The water that soaks into the soil finally rests upon an impervious stratum. Such water, as a rule, does not exist in the ground as a river<sup>c</sup> or lake, but occupies rather the spaces between the sandy particles, except in limestone formations. Ground water, therefore, in any quantity is found, as a rule, in sandy, gravelly, or sandstone formations.

<sup>c</sup>Leipzig and Pueblo both take their water supply from underground "rivers" flowing through coarse gravel. In Leipzig the stream is 2 miles wide, 40 feet deep and covered by 6 feet of soil; it probably represents the bed of an old river.

Ground water finally reaches a certain level, where it ceases to pass downward, and is then directed in a horizontal plane, forming a more or less continuous bed of water. This is known as the *ground-water table*, which underlies practically all of the earth's surface. It is tapped when wells are sunk, and forms springs, lakes and marshes, where it reaches the surface.

It is only in limestone regions that the ground water exists as flowing rivers or in large bodies. In such instances, as, for example, the mammoth cave in Kentucky, the underground river may appear and disappear suddenly. The sanitary significance of water from limestone crevices is entirely different from that obtained from a sandy soil.

The surface of the ground water does not follow the surface of the land, but more approximately the contour of the impervious stratum on which it rests. It crops out at the surface here and there, to form rivers, ponds, lakes, and springs. The irregularity of the surface of the ground water table is due to a certain extent to the rainfall. During drought the level becomes more and more uniform, until it may become quite horizontal.

**Movement.**—In most cases, except where water lies in deep depressions and pockets, the ground water is in constant lateral motion. This motion is usually in the direction of outfall, that is, toward the nearest large body of water—lake, river, or sea. That is why fresh water may frequently be obtained by sinking a well at the seacoast. In some places the rate of lateral flow is so slow as to be almost imperceptible; at other places it is comparatively rapid. Thus, at Munich, Pettenkofer estimated 15 feet per day; at Budapest, Fedor found the ground water to flow at an average of 167.6 feet per day. The rate of movement is dependent upon the pressure behind and the inclination or grade along which it flows. Slichter<sup>10</sup> estimates that with a temperature of 50° F. a porosity of 32 per cent. and a pressure gradient of 10 feet to the mile, water has been estimated to travel in a year in fine sand 528 feet, in medium sand 216 feet, in coarse sand 845 feet, in fine gravel 5,386 feet.

The method of determining the velocity of ground water which has been used with satisfactory results by Thiem is as follows:

Three or four borings are sunk to ground water in a line in the direction of flow. A large dose of salt is then put into the upper hole, and at frequent intervals analyses are made of water drawn from each hole below, until the salt content has reached its maximum in each case, and the rate of movement is computed from these results.

**Amount.**—The amount of water that may be obtained from the ground can only be determined by means of actual pumping tests car-

<sup>10</sup>Slichter, C. S.: "The Motions of Underground Waters," *Water Supply Paper* 67, U. S. Geological Survey, 1902.

ried on for a sufficient length of time to bring about an approximate state of equilibrium between the supply and the demand, as determined by the level of the ground water. It is rarely practical to continue such tests until perfect equilibrium is reached, for in many cases several years of operation would be required to determine the ultimate capacity of a source. Pumping tests of short duration are apt to be very deceptive, as ground water may exist in the form of a large basin or reservoir with very little movement, corresponding to a surface pond with small watershed, and brief tests would give little more information than similar tests on a pond.

It is easier in proportion to get a little ground water than to get a large amount, and for this reason ground water supplies are more generally available for, and better adapted to, the needs of small places than of large cities. In the United States, many small middle west communities are supplied with ground water from driven wells.

In Europe, ground water supplies have been secured for many large cities; there has been no corresponding development in America. The reasons for the greater use of this method of supply in Europe are: smaller quantity of water required per capita, more favorable geological conditions, and more study given to the subject and greater efforts to secure them, especially in Germany.

Ground water may be obtained from: (1) sand and gravel deposits, (2) sandstone rock, (3) limestone formations.

**Temperature.**—The temperature of ground water at a depth of 50 feet is practically constant and is the same as the mean atmospheric temperature of the region under which it lies. Below 50 feet the temperature increases  $1^{\circ}$  for each 60 feet in depth, on an average. Waters lying less than 50 feet below the surface are colder in winter and warmer in summer, as they are acted upon by external climatic conditions. Waters reaching the surface at hot springs must come from deep sources as many of them have a temperature of at least  $180^{\circ}$  F. Fuller states that springs with a temperature of over  $150^{\circ}$  F. are rare, if they occur at all outside of igneous regions. As this temperature represents only a depth of 5,000 feet it is readily seen that we have ordinarily no truly deep-seated springs whatever.

**Ground Water from Sand and Gravel Deposits.**—Water flows through sand with some difficulty. From a given pumping station it is only possible to draw the water from a limited distance. This distance depends upon the depth and coarseness of the sand. Therefore, the only way to secure a large quantity of water from such formations is by the use of a number of comparatively small pumping stations, separated so as not to draw from the same territory.

Only a given amount of water can be secured from a square mile of ground. The amount depends upon the rainfall, upon the evapora-

tion from the surface of the ground, from transpiration of vegetation, and upon the amount of storage in the pores of the soil.

Most of the sand deposits of our country are not practically available for water supply purposes, because the grains of sand are too small and the flow of water through them is too slow. It is only the coarse-grained sands that are practically available.

A few large cities in America obtain their drinking water supplies from ground water obtained from sand and gravel deposits. At Brooklyn the conditions are particularly favorable, and it is estimated that 78 million gallons of ground water are obtained each day for that borough of New York. For this purpose 24 separate pumping stations are used. The water supplied to Camden, N. J., is obtained from the ground through wells close to the Delaware River. This water filters through the sand slowly and is thus purified. This method of adding to the yield of wells is used in some places in Germany and France. Memphis, Tenn., is probably the largest city of the United States supplied entirely with water drawn from sand and gravel deposits. In this case the water-bearing area is several hundred feet below the surface, and is below a clay layer. Lowell, Mass., obtains ground water from three stations, draining different areas of glacial drift, while Baton Rouge obtains its water from an artesian well system 2,000 feet deep.

*Filter galleries* are excavations in sandy formations near river banks. Water from such sources corresponds in all practical respects to the ground water obtained from sand and gravel deposits by means of wells. The wells are preferable, as they allow water to be drawn at a lower level, and this tends to a drainage of a greater area, thereby securing a larger quantity of water.

Filter galleries are apt to furnish a diminishing supply, because the pores of the filtering material become filled with the sediment of the river water. When this happens there is no way of renewing the supply. In some torrential streams the filtering surface is renewed from time to time, but this usually does not occur.

Ground water obtained from sand and gravel deposits is usually clean and free from unwholesome impurities. Nevertheless, many towns and cities having such a supply were compelled to seek other sources, because sufficient water was not obtainable to supply rapidly growing population.

**Ground Water from Sandstone Rock.**—The method of driving wells in sandstone rock differs from that in driving wells in sand or gravel, but the collection, storage, and flow of water are precisely the same.

The cementing material, which binds what otherwise would be loose sand into a solid rock, often seems to offer but little resistance to the flow of water, and the sandstone for water supply purposes acts as so much sand would act.

Water drawn from sandstone is always well filtered. It, however, is usually limited in amount, and, while of the greatest value for small supplies, is not sufficient for large communities.

The Marshall and Potsdam sandstone underlying parts of Michigan, Illinois, Wisconsin, and Minnesota are used extensively for supplying towns and small cities. Thus, Jackson, Mich., with a population of over 25,000, is one of the largest cities so supplied.

**Ground Water from Limestone Formations.**—In limestone formations the underground flow of the water is not through sandy or porous rock, for limestone is not porous. The water travels through fissures or passages. When these are large they are called caverns or caves, as, for example, the Mammoth Cave in Kentucky. These caverns or caves are natural seams or cracks enlarged by the gradual solution and removal of the limestone by the passing water. Limestone is the only common rock that is soluble in this way, and, for water supply purposes, limestone formations must be distinguished from all others.

The crevices may be, and often are, continuous for many miles. They are remarkably tortuous and anastomose freely, and the direction and flow of the water bear no relation whatever to the surface topography. Pollution at one point may, therefore, endanger those using the water at a far distant place.

Limestone formation has little ability to hold the abundant winter flows to maintain a supply through droughts. The difference between limestone and sand in this respect is striking, and, from a sanitary standpoint, the fact that water flowing through sand is filtered and purified, whereas no such action takes place through limestone fissures, is significant. While much water is frequently available at one point in limestone formations, the amount is subject to greater fluctuations, and the supply may fall short when most needed.

That contamination at one point may soon reappear at a far distant point may be demonstrated by the use of fluorescent dyes, or by the use of massive cultures of some harmless microorganism, such as yeast or *Bacillus prodigiosus*.

In our country San Antonio, Texas, is supplied with water from limestone springs. Indianapolis was at one time and Winnipeg in Canada was also supplied largely from this source. Paris in France is partially supplied with limestone water. Vienna obtains its supply from the wonderful Kaiserbrunnen and other limestone sources, which are all in the high mountains, where there is scarcely any population or pollution. This supply is mainly from the melting ice and snow of the high mountains which replenishes the springs, so that the amount of water obtainable is greater in summer than winter.

Typhoid fever has been caused rather frequently by the use of ground water from limestone formations. This has been demonstrated in Paris,

Switzerland, France, England and elsewhere. Water supplies from limestone formations must, therefore, be regarded with suspicion.

**Wells.**—A well is nothing more or less than a hole sunk into the earth to reach a supply of water and fitted with some mechanical arrangement for lifting the water to the surface. Wells may be either shallow or deep, dug, drilled or driven. The type depends upon the nature of the material through which the well is sunk. By a shallow well is usually understood one which is dug and lined with stone or brickwork. The cylinder is usually 5 or 6 feet in diameter and rarely over 30 feet deep. Driven wells are made by driving an iron pipe into a sandy or gravelly soil. The iron pipe is perforated near its pointed end, for the entrance of the water. By deep wells are meant drilled or the so-called artesian wells. They consist of an iron pipe or tube 6 to 8 inches in diameter, and may extend many hundred feet into the earth. If the water is drawn from a depth of 100 feet or more without passing an impervious stratum, the well is usually spoken of as a deep well. If the well passes through an impervious stratum into a pervious one beneath, in which the water rests upon another impervious stratum, it is spoken of as an artesian <sup>11</sup> well. Water is usually pumped from the well either by means of the ordinary suction pump or by means of compressed air.

Contrary to the generally accepted opinion wells are usually polluted from the surface and not from the subsoil drainage. The filtering power of the soil is usually sufficient to protect the water drawn from

FIG. 106.—USUAL METHOD OF POLLUTION AND EVEN INFECTION OF WELLS.

<sup>11</sup> The word "artesian" is derived from Artois, an ancient province in France which was supplied with flowing wells. Artesian water may or may not flow spontaneously.

a well, unless (1) the soil is overburdened with organic matter, or (2) a cesspool, broken sewer, or other gross source of pollution is very close, or (3) channels, fissures, or crevices exist in the soil and subsoil

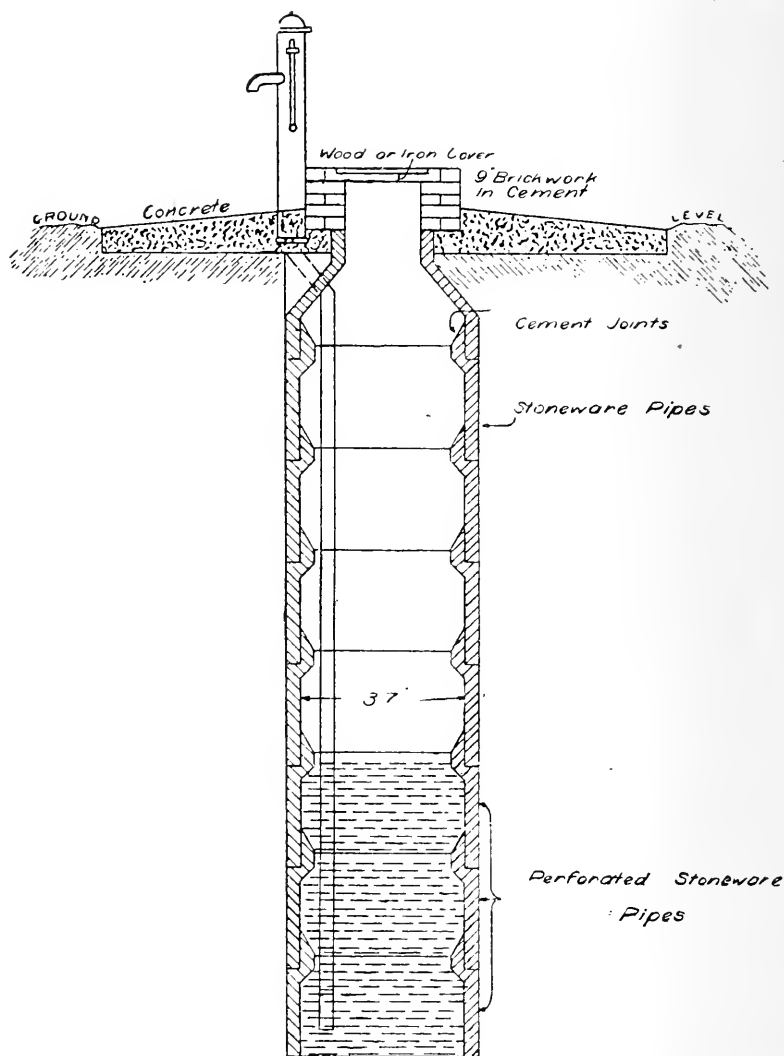

FIG. 107.—PROPER CONSTRUCTION OF A WELL, LINED WITH BELL AND SPIGOT VITRIFIED CLAY PIPE.

Design approved by the Rural District Council of Chelmsford, England.

so that impurities reach the well without undergoing the process of biologic filtration.

In locating a well, therefore, much depends upon the surface configuration of the ground, the character of the soil, and the proximity of

possible sources of pollution. The casing of the well should be sound and tight, preferably of brick laid in cement mortar, pointed on the inside. This impervious casing should extend as deeply into the well as practicable, and after it is laid the outer space between the casing and the earth should be filled in with well-tamped clay soil or concrete. One of the most important points in the construction of a shallow well is to extend the casing at least 18 inches above the surface of the ground and to build around it a shield of concrete or brick laid in cement extending in a circle from the top of the well 3 or 4 feet wide. This

FIG. 108.—POPULAR IDEA OF HOW WELLS BECOME INFECTED FROM SURFACE POLLUTION.

This probably rarely takes place in rural districts, as the soil can usually hold back most of the impurities. The danger is great, however, where fissures, cracks, or crevices exist, or where sewage enters beneath the surface of the soil from broken drains or leaky privies, especially in limestone formations.

shield should join the well casing so as to make a tight joint with the casing. The floor of the well should rest upon the top of the casing, so that no space is left for frogs, mice, or bugs to crawl in. The floor should likewise be water-tight, and is best made of reinforced concrete with a cement surface. If this is not practicable, it should be made of sound, hard, tongue-and-grooved boards well driven up, and the edges painted with white lead. Upon this should be laid another floor of similar material at right angles to the first. The pump should be let into the floor and firmly fastened to it, and protected with a flashing of tin to prevent water washing back into the well.

The widely prevalent idea that some form of ventilation must be provided for a well is entirely unnecessary. Well water keeps better in the dark and protected from the outer air and dust.

The top of driven wells should be as carefully protected as just described for a dug well, as otherwise the polluted surface water may work down the sides of the pipe. Care should be taken that the pipes of a driven well near the surface of the ground do not rust and become leaky. Such wells should be provided with a heavy top, to which the pump frame should be tightly bolted, in order to prevent the loosening of the joints in the pipe by the vibration of pumping. The space between the base and the well casing of driven wells should be filled with grouting and overlaid with cement near the top. The ground about all wells should slope away and be kept clean, and, where pos-

FIG. 109.—DEPRESSION OF THE GROUND WATER LEVEL BY PUMPING AND TENDENCY TO DRAW NEAR-BY POLLUTION FROM THE SOIL OR CESSPOOL.

sible, should be turfed. The waste water should be carried by pipes to a considerable distance from the well.

Artesian water and water from deep wells furnish the safest and most satisfactory sources of supply we have. Such water is usually clear and of high sanitary quality. Sometimes such waters contain a large amount of inorganic impurities, which render them unfit for domestic purposes. Frequently they contain iron in the ferrous state, which soon oxidizes upon contact with the air and is thrown out as an insoluble ferric salt, which renders the water yellowish or brownish. Deep well waters may also contain an excess of lime salts, common salt, manganese, or hydrogen sulphid, etc.

Water from shallow wells located in sandy or gravelly formations is entirely satisfactory, provided there are no nearby sources of pollution. The proximity of well and privy may be especially hazardous. Shallow wells in limestone regions must be carefully guarded and always looked upon with suspicion.

It is evident that in a densely inhabited area, with miles of sewers, some of them doubtless broken or leaky, and with the thousands of privy vaults which still survive in most of our American cities, we have a more or less sewage-polluted condition of the soil favorable for the contamination of shallow wells. Shallow wells, on general principles, have been gradually eliminated from all large cities having an abundant water supply. This danger was well shown in the studies upon typhoid fever in the District of Columbia, in which many of the shallow wells situated within the city limits were shown, by chemical and bacteriological analyses, to be polluted.

FIG. 110.—IN A LIMESTONE FORMATION IT IS DIFFICULT TO TELL ANYTHING ABOUT THE SOURCE OF WATER OBTAINED FROM A WELL.

Wells may be disinfected with lime, which has been found to be fairly effective. A mixture of carbolic acid and sulphuric acid in sufficient quantity will sterilize a well, but these substances have evident objections. The method of injecting steam under a pressure of two atmospheres has been used. The steam is forced into the water until the temperature is brought to near the boiling point. Bleaching powder, however, is the cheapest and most practical method of disinfecting wells that need such purification.

**Springs.**—A spring is a stream of water emerging from the ground, its flow being due to natural causes. Spring water does not differ in any essential particular from the ground water obtained from shallow wells. Springs may be regarded as natural wells, outcropping where the geological formation is favorable. Spring water, as a rule, is of a

high degree of purity, and as the water flows spontaneously it can easily be utilized; and, as no form of machinery is necessary to pump it, it is less subject to contamination than well water. Spring waters differ greatly in character, depending upon the temperature of the water and the inorganic constituents which it contains. Springs may be perennial, the flow being constant or intermittent.

Fuller classifies springs, according to their origin, as gravity and artesian; and according to the kind of passages traversed by the water, as tubular and fissure springs.

Some of the largest flowing springs are found in Florida, notable among these being the Silver Spring with an estimated flow of 368,913 gallons per minute, and Blue Springs with a flow of 349,166 gallons per minute.

Springs may be polluted from various sources, and in much the same way that wells are polluted. The overlying porous layer of soil may be too thin to remove the contamination of surface washings from privies, stables, hog pens, and other sources of contamination. This is probably not a frequent source of danger in such waters. Springs may be contaminated from surface washings; that is, the infective material may be washed down and into the spring by heavy rains, and, unless the spring has a bold flow, the polluting material may remain in it for some time. Leaky cesspools above a spring may carry dangerous material almost directly into the water, just as they endanger wells in precisely the same way.

The protection of a spring against contamination requires a careful study of each location. Stables, hog pens, and privies should be distant, and, if possible, on another slope. Soil pollution must be prevented in the neighborhood of the spring, and animals kept away, and special regard must be had for the location and character of the privy. The spring should be protected above with a masonry or concrete wall. This should extend well into the ground, so as to guard against surface washings. A ditch should be dug around both sides of the spring, to carry off the surface water and the neighborhood kept clear of weeds and growth. It is well to plant grass about the spring so as to keep out dust and prevent erosion of the soil.

In limestone regions springs are subject to the danger already spoken of in the case of wells. A spring in such a region may be the same underground stream that runs through the neighbor's back yard and disappears in his meadow. A limestone spring that becomes muddy soon after a rain should be regarded as particularly suspicious.

## THE SOURCES AND NATURE OF WATER POLLUTION AND INFECTION

A distinction is drawn between a polluted and an infected water. A polluted water is one that contains organic matter and the products of decay, either of vegetable or animal origin. An infected water is one that contains the specific parasites causing disease. A polluted water may not be particularly harmful to health; it is suspicious. That is, a polluted water is not necessarily infective; an infected water is practically always polluted. Practically all surface waters are polluted; ground waters usually show evidence of past pollution; that is, they contain inorganic salts in solution resulting from the mineralization of organic matter.

The greatest hazard to man is found in a water polluted with the discharges from the human body—feces, urine, and sputum. There is comparatively little danger from water containing the wastes of other animal life, for the reason that few of the infections of the lower animals are thus transmissible to man. There is still less danger in water contaminated with organic matter of plant origin. Water containing small amounts of inorganic substances in solution plays a relatively minor rôle, as far as health is concerned.

From a sanitary standpoint, then, it is the wastes of human life that concern us especially. These may enter a surface water directly from overhanging privies, or from sewers, or from washings of the land. Ground water becomes polluted in ways already discussed.

The prevention of the pollution of our streams, lakes, ponds, and other surface supplies is an important sanitary problem with a large economic side. As far as streams and large lakes are concerned, the most dangerous infection is that which is nearby—that is, that which is quickly transferred in a fresh and virulent form. Distant infection is much less dangerous. Cities taking water from an average stream should prevent the access of direct pollution for at least 50 miles, or better 100 miles, above the intake. Partial protection may also be accomplished by requiring sewage disposal works for all towns and settlements, and abolishing all overhanging privies upon the river and its tributaries. A sanitary inspector could cover a large area for this purpose. When these measures are not feasible, intercepting sewers may be built, as on the Schuylkill at Philadelphia. Canals that parallel a river, as the one upon the bank of the Potomac, may receive the sewage and surface drainage and thus protect the stream. It is comparatively easier to guard smaller lakes and ponds and impounding reservoirs.

**Simple Tests to Determine Sources of Pollution.**—Sources of pollution and possibly of infection may often be determined by simple tests

which may be carried out by a layman. These tests afford valuable information and consist in the addition of some chemical substance to the source from which pollution is possible and then determining whether the same reappears in the water supply. For this purpose a large number of substances that may be readily recognized by their taste, odor, or appearance may be used, such as coal oil, carbolic acid, fluorescein, and common salt. Coal oil poured near the ground of an artesian well is an easy and convincing method of establishing the presence of defective piping and surface or subsoil contamination. Nördlinger recommends for this purpose saprol, which tastes like naphtha and is so penetrating that its odor may be readily recognized in proportions of 1-1,000,000 or by taste in solutions of 1-2,000,000. Trillat experimented with a large number of dyes and finds that fluorescein dissolved in alcohol and diluted with 5 per cent. ammonia solution can be detected by a fluoroscope in proportions of 1-2,000,000,000. The fluoroscope is a tube of clear glass three or four feet long and one-half inch in diameter, closed at one end with a rubber cork. In such a tube natural waters have a somber blue color which changes to a clear green if fluorescein is present. Fluorescein can be detected by the unaided eye in dilutions of 0.625 part per million. This dye possesses the evident advantage of not being precipitated by the soil ingredients, a reaction that readily occurs with most aniline dyes brought in contact with calcareous solutions. Salts of lithium are sometimes used, for they may be detected in the minutest traces if the water is examined by the aid of a spectroscope.

The conclusion must not be drawn that because these soluble salts reappear in the water microorganisms and dangerous pollution would likewise find its way through the soil for an equal distance, for the soil has well-known filtering power when free from fissures or open channels and is capable of removing bacteria and oxidizing large quantities of organic matter. However, these methods are of service in indicating the possibility of danger under certain circumstances and are particularly useful in discovering sources of pollution near wells or in limestone formations.

Massive cultures of prodigiosus, pyocyaneus, fluorescens, yeasts, and other microorganisms if not normally present in the water under examination may be used to detect the possibility of infection. The cultures are poured upon the ground or into suspicious places and the water tested at varying intervals to determine whether they reach the supply. Careful controls must be made beforehand to assure the absence of the particular organism used.

**The Interstate Pollution of Streams.**—Sanitarians have maintained for years that no community or individual has a right to pollute streams used for public water supplies, any more than a man has a right to poison his neighbor's well. England enjoyed the benefit of a Rivers

Pollution Commission as early as 1855, in order to prevent, remedy, and remove the danger of polluted water supplies. This commission adopted a comprehensive system for the disposal of sewage and for water purification, the fruits of which England is enjoying today. This country has no law regarding the interstate pollution of streams, and with our growing population and increasing amount of pollution this is becoming a live and pressing sanitary question. After the Chicago drainage canal was opened the city of St. Louis (state of Missouri) sued the city of Chicago (state of Illinois) through the federal courts, asking an injunction against the pollution of the Mississippi River, from which St. Louis draws its drinking supply. The testimony occupied many weeks, and in published form takes up many volumes. The verdict was "no cause for action," or "not guilty," that is, it was not proved that typhoid bacilli or other organisms dangerous to health reached St. Louis from Chicago.

The principles of common law as to interstate waters have been appreciated by some of the nations of Europe. Thus, the inhabitants of a town in Belgium suffered from the effects of a river polluted by the French, and the French government not only compelled the offending city to dispose of its sewage by irrigation, but granted a subsidy for this purpose. In some of our more progressive states, as, for example, Massachusetts, Pennsylvania, Connecticut, Minnesota, New Hampshire, New Jersey, New York, Vermont, and others, the State Board of Health is given control over the pollution of streams within the borders of the state.

Speaking generally, jurisdiction over the pollution of waters in the United States is confined to the several states. There is no provision in the Constitution which gives to Congress authority in the premises. Hence, by the familiar principle in our Constitution that the several states retain full sovereign power, except so far as such powers are restricted by the national Constitution or expressly delegated thereby to the national government, the individual states have full control of this subject—a subject with which they are individually impotent to deal and which logically belongs to the federal government.

**Pollution of International Boundary Waters.**—Under terms of Article IX of a treaty of January 11, 1909, between the United States and Great Britain, the questions of extension of pollution of boundary waters and remedies were referred to the International Joint Commission under date of August 1, 1912. A sanitary survey was made of the Great Lakes District, particular emphasis being laid on sewage pollution from cities and towns, sewage from vessels, saw mill and other industrial and household wastes, and present methods for their control. In general, the conclusions embodied in their final report, 1919, are that it is "feasible and practicable without imposing an unreasonable burden

on the offending communities to prevent or remedy pollution, both in the case of boundary waters and waters crossing the boundary. In case of city sewage, this can best be accomplished by installing collection and treatment works having special reference to the removal of bacteria and matters in suspension." The conclusion is made that vessels should treat their sewage before discharge, as for instance with live steam, also that water ballast discharge be regulated with due regard for drinking water intakes for any neighboring community; further, that restriction should be placed on disposal of garbage and carcasses in boundary waters.

**The Care of Catchment Areas.**—"Catchment area," "watershed," "drainage area," and "catchment basin" are terms used to include the area immediately surrounding a water supply so situated that water falling upon it will be directed toward this supply. The ideal catchment area is free from human habitation and is covered with forests. The catchment areas supplying impounding reservoirs and the natural ponds and lakes used as reservoirs are limited in area when compared, for example, with the catchment areas of the great rivers, from which many public water supplies are drawn. It is, therefore, possible to inspect and control the former more readily than the latter.

It is often impossible to remove population from a catchment area, and, in fact, it is usually unnecessary to do so. Very good water may be drawn from areas upon which there is a large population, when proper and well-known precautions are taken. Thus, there are 776 people per square mile upon the Cochituate catchment area, 282 upon the Sudbury, 49 upon the Wachusett, furnishing Boston's water supply, and 59 upon the Croton, furnishing New York's water supply.

The prolonged storage of the water in large protected reservoirs is a sanitary safeguard, and makes the Boston water and the New York water safer than it otherwise would be. The greatest danger is that some polluted water will sometimes get by the reservoir or flow through it by some short circuit, as surface currents or by-passes, and so reach the consumer, before it is subjected long enough to full storage conditions.

The proper sanitary care of a catchment area requires, first of all, sufficient laws granting suitable authority, especially concerning the disposal of human wastes.

Care must also be exercised to keep out manufacturing wastes and the surface washings that may carry pollution from human sources or undesirable contamination from other sources. This object may be accomplished in various ways. The city should own the shores of the reservoirs and also as much of the land along the important streams as is necessary to carry out these objects. Old sources of pollution must be removed, and new sources not permitted. Where the danger from human pollution is especially great, as around the impounding reservoir itself or at nearby suburban settlements, engineering projects, some-

times of considerable magnitude, are necessary to carry away the sewage and the surface drainage. A strict patrol of the catchment area, in order to supervise picnic and camping parties, the camps of construction gangs, and other sources of danger, must be exercised. A good man on the alert can patrol a large district, getting his information through various ways, and personally inspecting all suspicious localities frequently.

In the investigation of a stream and its watershed the chief points requiring attention are the relative proportions of the polluting matter and the flow of the river when at its minimum; the general character of the stream, the rate of flow, and the distance between the source of pollution and the intake of the water.

Many Water Boards, having control of large tracts of land, are planting their catchment areas with trees with advantage and profit. It is found that the presence of trees adds to the retention of water falling as rain, lessens evaporation, and cools the adjacent atmosphere, perhaps aiding condensation. Trees prevent floods, regulate and help to purify the supply, for water draining through the soil of wooded areas is naturally cleaner than that scouring the surface of barren land.

## CHAPTER II

### SANITARY ANALYSIS OF WATER

A complete sanitary analysis of water includes: (1) a *physical examination* to determine color, turbidity, odor, and taste; (2) a *microscopic examination* to determine the number and character of particles in suspension, especially algae; (3) a *chemical analysis* to determine the nature and amounts of chemical impurities; (4) a *bacteriological examination* to estimate the number and kind of bacteria; (5) a *sanitary survey* of the watershed, including the methods of collecting, storing, handling, and distributing the water; and (6) *clinical result*, which, after all, is the final test, for water may contain impurities or qualities detrimental to health that are not recognizable by any other method. Thus, the water supply of Vienna from the famous Kaiserbrunnen is particularly pure, as determined by laboratory analysis. Nevertheless, this water, owing to a lack of iodine, is responsible for the great increase in the number of cases of goiter which has been observed in Vienna since its introduction.

Water is particularly liable to contamination under prevailing conditions and must, of necessity, demand increasing watchfulness and a continual readjustment of restrictions governing its use.

The fact that water is the most universal solvent known is not to be neglected. The water we drink has come in contact with the earth and many other substances. It dissolves many organic and many inorganic impurities, few of which can be detected in the laboratory by the routine methods used. The influence of many of these substances upon health is unknown. Exceedingly small amounts of poisonous substance in water may act injuriously when we recall how much water is daily taken. All these facts should make us cautious before we give a water supply a clean bill of health, and communities will find it pays in the end to go to great expense to improve this important article of daily use.

**Standard Methods.**—The advantages of using a standard method are self-evident; it at least gives results that are fairly comparable with the work of others. The standard methods for water analysis have been carefully considered by a competent committee of the American Public Health Association. The first report was published in the *Journal of*

*Infectious Diseases*, Supplement No. 1, May, 1905.<sup>1</sup> Amendments and improvements to the method are published from time to time. For anyone not having special skill in chemical analysis or bacteriological technic it is advisable to adhere closely to the standard procedures. Any deviation from these methods should always be noted in published reports. Because a method is "standard" does not mean that it has a fixed and permanent value as a model to be blindly followed under all circumstances. Standard methods are established by common consent as the rule to be followed under ordinary circumstances, especially for routine work and by those who are not especially skilled in laboratory technic. For reasons that seem self-evident, it is of special importance to follow the standard methods for bacterial counts.<sup>2</sup>

Our standards by which the purity of water is judged are constantly rising. There is no doubt that many waters now considered safe and wholesome will not be acceptable in the future.

**Collection of the Sample.**—For a complete physical, chemical, and microscopical analysis of water one liter is necessary. If the sample has been collected in a sterile container with precautions to prevent contamination the same sample may serve for the bacteriological examination. Usually the bacteriological samples are collected separately in special bottles holding at least 100 c. c.

The bottles should be of hard, clear white glass and have a glass stopper. They should be chemically clean and dry sterilized at 160° C. for 1 hour, or in the autoclave at 115° C. for 15 minutes. For transportation they may be wrapped in sterile cloth or paper, but, better, the neck may be covered with tinfoil and the bottle placed in a tin box. When bacterial samples must of necessity stand 12 hours before plating, bottles holding more than 4 ounces should be used. Cork stoppers should never be permitted, except when physical or microscopical examination only is to be made. Earthen jugs and metal containers are entirely unsuited.

Generally speaking, the shorter the time elapsing between the collection and analysis, the more reliable will be the analytical results. If too long a time intervenes, it affects especially the bacterial tests, for bacteria multiply enormously when water is kept in a bottle at ordinary temperature. The oxygen consumed, oxygen required, and nitrites are also materially affected by comparatively short delay.

In general, water must be analyzed as soon as possible after sampling.

<sup>1</sup>The fourth edition can be obtained from the secretary of the association, 169 Massachusetts Avenue, Boston, Mass.

Bacteriological standard for Drinking Water. U. S. Public Health Reports, Nov. 6, 1914.

<sup>2</sup>In the methods for water analysis described in this book the standard methods have been closely followed, and due acknowledgment is here given to the splendid and self-effacing work of the committee that devised them.

The following are the maximum times allowed by the Standard Methods of the American Public Health Association:

*Physical and Chemical Analysis:*

Ground waters .....	72	hours
Fairly pure surface waters.....	48	"
Polluted surface waters.....	12	"
Sewage effluence.....	6	"
Raw sewages.....	6	"

*Microscopic Examination:*

Ground waters.....	72	"
Fairly pure surface waters.....	24	"
Waters containing fragile organisms .....	Immediate examination should be made in situ if practicable.	

*Bacteriological Examinations:*

Samples at less than 10° C.....	24 <sup>3</sup>	hours
---------------------------------	-----------------	-------

Care should be taken to secure a sample which is thoroughly representative of the water to be analyzed. A pump should be operated five minutes, or water faucet allowed to run several minutes, before the bottle is filled. In collecting samples of surface waters the specimen should not be obtained too near the bank of the stream or pond. A note should be made as to whether the specimen is collected from the surface or at what depth under the surface it is taken. It is always advisable to take the temperature of the water at the time of collection.

## ODORS AND TASTE

The purest water is absolutely devoid of taste and odor, but it is also insipid. If such water is aerated by agitation or by filtration through a porous air-containing substance, it becomes sparkling and agreeable. The taste is imparted to most waters by the mineral matter as well as the gases held in solution, hence the flat, insipid taste of distilled water. After a person becomes accustomed to the taste of a particular water another does not appeal to him and does not satisfy his thirst to so great an extent. Once having been accustomed to a moderately hard water, a soft water is very flat and tastes much like distilled or rain water.

Odors in waters are objectionable, rather than detrimental to health. As a rule, the most objectionable odors develop in surface waters and are caused by the growth of algae, diatoms, protozoa, and other microscopic beings. Industrial wastes are sometimes responsible for odors

<sup>3</sup> Formerly only 6 hours were allowed. The results will be more truly representative of the bacteriology of the water, the shorter the time between collection and analysis.

and tastes. The earthy odor of some ground waters is due to substances taken up during the passage of the water through the soil. When a well water becomes offensive it is evidence of stagnation at the bottom of the well or the presence of dead animals. In the case of deep wells hydrogen sulphid and other inorganic compounds may impart odors to the water. The odors and tastes which develop in impounding reservoirs from stagnation and putrefaction of the organic matter have been discussed on page 1030.

On the whole, the waters of natural lakes and ponds are less subject to objectionable odors and tastes than are the waters of artificial reservoirs, and putrefaction is less troublesome, but the difference is one of degree, not of kind.

The power of water to dissolve or absorb gases and odors is an important one, and explains how water may become "contaminated" by mere exposure to an impure atmosphere, as when an uncovered cistern is placed in a water-closet or when an overflow pipe is directly connected with a drain.

**Method of Determining Odor.**—The odor of the water should be observed both at room temperature and just below the boiling point. Odors should be determined at room temperature (20° C.) by shaking a sample violently in a gallon collecting bottle when it is half or two-thirds full; and by heating about 150 c. c. in a 500 c. c. Erlenmeyer flask and covered with a well-fitting watch glass. In either case care should be taken to observe the character of the odor the instant the receptacle is uncovered. The kind of odor observed may be described as vegetable, aromatic, grassy, fishy, earthy, moldy, musty, disagreeable, peaty, sweetish, etc., and the intensity by such terms as very faint, distinct, decided, or very strong.

The odors and tastes in water caused by microscopic organisms deserve special consideration, because they are common faults in water stored in open artificial reservoirs of all kinds. Certain organisms can be distinguished by their odor, as, for example, the "fishy" odor of *Uroglena*, which is a protozoön and classed with the *Infusoria*; the "aromatic" or "rose geranium" odor of *Asterionella*, which belongs to the *Diatomaceae*; and the "pig-pen" odor of *Anaboena*, which is one of the blue-green algae.<sup>4</sup> These microscopic organisms mostly grow near the surface and require sunlight for their development; hence, odors produced by them never occur in covered reservoirs or in waters kept in the dark.

Calkins has shown that the odors caused by the undecomposed microscopic organisms are due to compounds of the nature of essential oils, and Whipple points out that the amount of such oil produced by an

FIG. 112.—ALGAE COMMONLY FOUND IN WATER.

abundant growth of the organisms is quite sufficient to account for the effect observed. He notes for comparison that oil of peppermint can be recognized when diluted with water in the proportion of one part of oil to fifty million parts of water, and that when *Asterionella* is present to the extent of 50,000 organisms per c. c. the dilution of its oil is in the proportion of about one part to two million parts of water. Whipple further suggests that the flow of water through pipes may cause disintegration of organisms with liberation of the odor-producing oil, hence the odor at the tap may be greater than at the intake.

The *Algae* responsible for the vile tastes and odors in water do not depend upon organic matter or the bodies of other organisms for their food supply. They require only carbonic acid and the nitrogen and

FIG. 113.—THE OIL DROPLETS IN A DIATOM.

mineral matters always present in the water and in the air, and the sunshine for their growth. In other words, they have properties comparable in many respects to the higher orders of chlorophyll-containing vegetation.

There are very many kinds of algae, and they differ greatly in their odor-producing powers. Most American impounding reservoir waters suffer from them, but some far more than others. English reservoirs seem to be comparatively free from this nuisance, probably because of the lower temperatures of the surface waters. There is an average difference of at least 10° F. between the surface temperatures of English and American reservoirs.

A certain degree of quiet and repose is necessary for the development of a large growth of algae; that is why they never develop to any extent in rivers and flowing water. Wave action from wind also prevents growth, and this seems to be the only reason why large lakes and reservoirs are less troubled by them than smaller ones.

In most American impounding reservoirs the water is drawn from near the surface layer, so as to avoid the odors and tastes of putrefaction in the bottom water, but it sometimes happens that the surface water is the more objectionable.

**Prevention and Removal of Tastes and Odors.**—The natural flow of water in the bed of a mountain stream over stones and ledges aerates it very well. This is nature's method of removing undesirable tastes and odors. Aëration may also be accomplished by bringing the water in contact with the air by devices such as fountains, waterfalls, etc. Such aëration always reduces, and sometimes removes, tastes and odors from the waters of reservoirs and small lakes, whether resulting from putrefaction in the stagnant bottom water from growths or organisms in the surface water, or from gases held in solution.

In general it may be stated that filtration alone is not efficient in removing tastes and odors; however, slow sand filtration has considerable power of reducing, and in some cases of removing, tastes and odors, but it cannot be depended upon when the raw water is very bad.

Intermittent filtration is particularly successful in removing tastes and odors. It is successful because it brings the organic matter in contact with more air and in more intimate contact with air, and for a longer time in the pores of the sand, than can be secured in any other way.

It is practically impossible to prevent the seeding of reservoirs and ponds with algae and other organisms responsible for the objectionable odors. The growth may be checked and the odors temporarily controlled by the use of copper sulphate. See page 1143.

If a well becomes stagnant at the bottom, and thus develops vile odors from putrefying organic matter, the trouble may be corrected by lowering the pump to near the bottom so as to prevent stagnation, or by filling up all unnecessary space with clean gravel and sand.

## COLOR

Pure water, when viewed in small quantities, appears to be perfectly colorless, but, when viewed in bulk, as in the white-tiled baths at Buxton, and in certain Swiss lakes, it is seen to possess a beautiful greenish-blue tint. A very small amount of suspended or dissolved impurity is sufficient to obscure this color.

Impure waters almost invariably exhibit a color varying from green to yellow and brown, when examined through a depth of two feet in suitable tubes. It does not, however, follow that a colored water is, therefore, polluted or infected.

Color in surface water is usually of vegetable origin; animal matter contributes but little color. The coloring matter is extracted largely from dead leaves, bark, and roots, from soil, and from peat. It seems to be the same material as the coloring matter of tea. It is certainly harmless, but it makes the water less pleasing in appearance, and great efforts have rightly been made to prevent and remove it. Water from swamps is usually highly colored, the degree of color depending upon the length of exposure.

Ground waters are usually colorless. If the water contains iron it will be perfectly clear on coming from the ground, but will soon turn a rusty yellow color. This is caused by the oxidation of the soluble ferrous salts to insoluble ferric salts.

Color in water should be distinguished from turbidity. True color

is due to dissolved impurities, turbidity to substances in suspension. The "apparent color" is the color of the original sample, due to both dissolved and suspended matter.

The prevention of color in surface waters consists in draining swamps. Thus, in the catchment areas of the various reservoirs supplying Boston thousands of acres of swampy land have been drained for the purpose of reducing the color of the supplies, and with good results.

A colored water may be bleached by exposure to sunlight and air, but the bleaching of the water in reservoirs requires great storage capacity, and the drainage of swamps is likewise very expensive. Ozone applied in large amounts also destroys color, and the only objection to its use is the cost. Oxygenated compounds of calcium, sodium and chlorine will also bleach a colored water.

About 20 per cent. of the dissolved color in water may be removed to a considerable extent by slow filtration through sand. If the coloring matter is first rendered insoluble by the use of coagulants (sulphate of alumina), it is readily removed by filtration.<sup>5</sup> Color is thus successfully removed from the waters used by Norfolk, Va., Charleston, S. C., and Watertown, N. Y. Sulphate of iron is less satisfactory as a coagulant than sulphate of alumina for the removal of color.

**Method for Estimating Color.**—Turbid waters should always be filtered before the color observations are made. The intensity of color may be determined by comparing with a standard platinum-cobalt solution; the tint or shade may be determined by comparison with the standard color disks of the United States Geological Survey or a Lovibond tintometer.

*Platinum-Cobalt Standard.*—The standard solution, which has a color of 500, is prepared as follows:

Dissolve 1.246 grams of potassium platinic chlorid ( $\text{PtCl}_4 \cdot 2\text{KCl}$ ) containing 0.5 gram platinum, and one gram crystallized cobalt chlorid ( $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ ) containing 0.25 gram of cobalt in water, with 100 c. c. concentrated hydrochloric acid, and make up to one liter with distilled water.

By diluting this solution with distilled water to the 50 c. c. graduation mark on the Nessler tubes, standards are prepared having colors of 0, 5, 10, 15, 20, 25, 30, 35, 40, 50, 60, and 70. These should be kept in Nessler tubes of such diameter that the 50 c. c. graduation mark is between 20 and 25 cm. above the bottom, and is uniform for all tubes. They should be protected from dust and light when not in use.

*Procedure.*—The color of a sample is observed by filling a standard Nessler tube to the graduation mark with the water to be examined, to a depth equal to that of the standards, and by comparing it with the standards. The observation should be made by looking vertically down-

<sup>5</sup> For the reactions with Alum see page 1141.

ward through the tubes upon a white surface placed at such an angle that light is reflected upward through the column of liquid.

Waters that have a color darker than 70 should be diluted before making the comparison, in order that no difficulties may be encountered in matching hues.

## TURBIDITY

Practically turbidity is synonymous with muddiness. The turbidity of surface waters is usually due to mud, clay or silt, also to finely divided organic matter, microscopic organisms, and a great variety of objects. Turbidity represents the amount of foreign substances in suspension; it is frequently, though incorrectly, spoken of as color. In a general way turbid waters exist in those regions where color is not found; the former represents the washings of a readily eroded drainage basin, the latter is mostly extracted from the decaying vegetation of swamps.

Pure water is clear and sparkling, in proportion to the amount of dissolved oxygen and carbonic acid. While brilliancy and clearness do not mean purity, on the other hand turbid waters are not necessarily dangerous. A community for years may drink and seem satisfied with a turbid water that is little less than liquid mud. This was formerly the case with Washington and the Potomac water, St. Louis and the Mississippi and many other cities. When, however, such a city once appreciates the beautiful appearance of a clean water, they complain if the turbidity reaches the point of a faint opalescence. The turbidity question is practically limited to river waters. Ground waters should never be turbid, and, if so, should at once excite suspicion. Some ground waters become more or less turbid through the precipitation of iron.

All river waters are more or less turbid, but the differences are very great indeed. The amount of turbidity depends largely upon the character of the catchment areas. In general, rivers draining the large areas of our North and East, covered with glacial drift of a sandy character, are but little subject to turbidity. Thus, on an average, the Merrimac and Connecticut Rivers do not carry more than 10 parts per million of suspended matter. In that part of our country which is not glaciated, and this includes the lower Susquehanna basin, much of the Ohio basin, and the Missouri basin, and all to the south of them, turbidity is often present in large amounts, and consists largely of clay in extremely fine particles. The water often runs turbid in these streams continuously for weeks and even months at a time. The Missouri River carries the largest amount of sediment of any of our rivers largely used to supply water. The annual average runs as high as 1,200 or 1,500 parts of sandy matter per million. In winter it falls to 200 parts

or less, while in midsummer it rises for weeks and even months to 5,000 parts or more.

If the turbidity is sufficiently coarse-grained it may be removed by sand filtration without previous chemical treatment. Very turbid waters can be cleared, in part, in settling basins; this lightens the work of the filters and reduces the cost. Scrubbers, which are preliminary rough filters, may also be used to protect the sand filters. In many instances the individual particles of clay which make up the turbidity are much smaller than the bacteria. They will not settle out, even after prolonged storage, and they cannot always be removed by filtration alone. There is only one known way of removing such turbidity, and that is by coagulation or chemical precipitation. The substances most commonly used for this purpose are: aluminum sulphate, alum, or sulphate of iron. See page 1141.

This is successfully done with very muddy supplies at New Orleans, Nashville, Richmond, St. Louis and many other river towns.

With reference to the influence of the suspended matter upon health we find some conflict of opinion. Kober states that water containing 50 parts per 100,000 or 30 grains of solid matter per gallon is unfit for drinking purposes, on account of its irritating effects upon the gastrointestinal tract. Apart from this, turbidity appears to have no special sanitary significance.

**Methods for Estimating Turbidity.**—There are three methods by which the degree of turbidity may be determined: (1) the platinum wire method, which consists of determining the depth of water through which a platinum wire of standard diameter may be seen; (2) comparison with waters of standard turbidity, made by adding 1 gram of Pear's "precipitated fuller's earth" sifted through a 200-mesh sieve, to 1 liter of distilled water; this is known as the silica standard; and has a turbidity value of 1,000; (3) the amount of suspended particles in water may be determined in special instruments known as turbidimeters or diaphanometers. These instruments consist of a graduated glass tube with a flat polished bottom, inclosed in a metal case. This is held over an English standard candle, and so arranged that one may look vertically down through the tube and see the image of the candle. The observation is made by pouring the sample water into the tube until the image of the candle just disappears from view. The graduations on the tube correspond to turbidities produced in distilled water by certain numbers of parts per million of the silica standard.

The standard of turbidity adopted by the United States Geological Survey<sup>6</sup> consists of a water which contains 100 parts of silica per million, in such a state of fineness that a bright platinum wire 1 millimeter in diameter can just be seen when the center of the wire is 100 milli-

<sup>6</sup>U. S. Geol. Survey, Div. of Hydrography, *Circular No. 8*, 1902.

meters below the surface of the water and the eye of the observer is 1.2 meters above the wire, the observations being made in the middle of the day in the open air, but not in sunlight, and in a vessel so large that the sides do not shut out the light so as to influence the results. The turbidity of such water is taken as 100, and all turbidity readings, no matter what method is used, should conform with this method.

Where only an occasional analysis is made for general purposes it is sufficient to record the sediment and turbidity as very slight, distinct, or decided.

Turbidity determinations should be made as a routine to help guide the efficient and economic operation of a filter plant; especially where a coagulant is used, to fix the dose.

## REACTION

The alkaline reaction of natural waters ordinarily depends upon the carbonate and bicarbonate of calcium and magnesium. In some waters in the West it also includes the carbonate of sodium and of potassium. The alkalinity of water is determined by titrating 100 c. c. of the sample with  $\frac{N}{50}$  sulphuric acid, using 4 drops of a solution of lacmoid as an indicator. The lacmoid solution consists of 2 grams in one liter of 50 per cent. alcohol. The last cubic centimeter or two of acid must be added while the sample is almost at the boiling temperature, and the end reaction is not read until a drop of acid, striking the surface of the liquid, sinks to the bottom of the dish without producing a change in the uniform reddish or purplish color of the solution. Erythrosin may be used as an indicator when it is desired not to use heat. The number of cubic centimeters of  $\frac{N}{50}$  sulphuric acid used, when multiplied by ten, gives the number of parts per million of alkalinity in terms of calcium carbonate.

Under certain circumstances rain water, water from peat bogs, and water from coal mines, tanneries, etc., have an acid reaction. In mining regions waters are frequently acid from high quantities not only of  $\text{CO}_2$ , but also of sulphuric acid and various sulphates—those of iron and aluminum giving an acid reaction. When these are present, the total acidity is determined by titrating the water in the cold with a  $\frac{N}{50}$  sodium carbonate solution, using 4 drops phenolphthalein as an indicator. The calculation is the same as that for alkalinity.

Mine water is that which is constantly flowing from the coal and surrounding strata. It is collected in ditches at one side of the gangways and tunnels, and is allowed to flow to the lowest point in the mine or to the foot of the shaft, from which it is pumped to the surface.

Large quantities of this and other water are used to wash the coal. This water is acid. The spent tan liquors from tanneries are also acid.

Rain water collected in the vicinity of towns has usually a slight acid reaction and acts upon lead. The free acid in rain water is apparently sulphuric, no doubt derived from the sulphur in the coal burned.

Water from marshes, swamps, and especially from peat bogs may have a markedly acid reaction, especially in dry weather, when the flow will be comparatively small. Heavy storms wash out the water which has long been in contact with the decaying vegetation. The acidity in this case is due to organic acids.

When the collection of an acid water cannot be avoided, arrangements should be made for adding lime or some other suitable alkaline substance capable of completely neutralizing the acid, as without some such arrangement the consumers of the water run the risk of lead poisoning, provided lead service pipes are used. A river water suddenly turning acid in reaction plays havoc with a slow sand filter. This has occurred in the Pittsburgh filter.

### TOTAL SOLIDS

The total solids or residue on evaporation is obtained by evaporating a given quantity of water to dryness, when a grayish-white residue, composed of mineral and some organic matter which has been held by the water in suspension and in solution, will be obtained. The amount of this residue varies with the character of the water, and furnishes an index of the total quantity of foreign impurities, and further furnishes a rough index of the relative quantity of inorganic and organic substances which make up these impurities.

**Method.**—Place 100 c. c. of the water in a clean platinum dish. Evaporate to dryness on a water bath, and finish the evaporation for one hour or to constant weight in an oven at 103° C. to 180° C. The temperature used should be mentioned in the report. Now place the platinum dish in a desiccator over sulphuric acid until cool, and weigh. The increase in weight gives the total solids, or residue on evaporation. This weight in milligrams multiplied by 10 gives parts per million.

The platinum dish containing this residue is now heated to a dull red heat. Allow the dish to cool and moisten the residue with a few drops of distilled water. Dry the residue in an oven, cool in a desiccator and again weigh. The difference in weight is called the "loss on ignition," and the weight of the substances remaining in the platinum dish is known as the "fixed residue." The loss on ignition is an index of the amount of organic matter in the water. A portion of the loss, however, may be due to ammonia or other volatile compounds and un-

stable mineral salts. The fixed residue is an index of the mineral content of the water. With waters low in organic matter, but relatively high in iron, the fixed residue is occasionally used as a matter of convenience for the determination of iron. In water analysis it is usual to note the character of the odor upon ignition of the residue. This may be earthy, or may suggest organic matter of vegetable origin or animal origin. Such determinations have little value in determining the sanitary character of a water.

The amount of total solids in a water depends upon the character of the soil with which the water has been in contact, the length of exposure, and the amount of carbon dioxide in the water to favor the solution of inorganic salts. Some mineral springs contain very large amounts of total solids, derived from deeply situated natural deposits, as, for example, the springs at Saratoga, Carlsbad, Kissingen, etc.

The permissible amount of solids as represented by the residue on evaporation, which consists of the dissolved mineral constituents, cannot be arbitrarily stated, but 500 parts per million are generally held as excessive.

## HARDNESS

Hard water is objectionable because it wastes soap and affects the skin unpleasantly; it is less satisfactory than soft water for cooking and washing; it produces scale in boilers and is objectionable in some industries such as paper mills. The traveler is unpleasantly reminded of the effect of abruptly changing from a soft to a hard water, or vice versa, which results in simple gastro-intestinal disturbances, which are temporary in effect. Hardness in water is more of an economic question than one of sanitary interest, except, perhaps, as the encouragement of the use of soap and cleanliness is of fundamental importance in hygiene and sanitation. Hardness in water is due to the presence of the soluble salts of the alkaline earths—especially calcium and magnesium. These salts form a curd with soap instead of a lather, hence more or less soap must be wasted in decomposing the lime and magnesia compounds before a lather will form. Thus, one grain of calcium carbonate, for example, will use up 8 grains of soap before a lather can be produced; in this way hard water causes an enormous waste of soap. In Europe, hardness is usually expressed in degrees. Each degree corresponds to one grain of carbonate of lime or its equivalent of other lime or magnesium salts in a gallon of water.

The hardness of water is called "temporary" or "permanent," depending upon the solubility of the salts it contains. Temporary hardness is due to calcium or magnesium carbonate held in solution as a bicarbonate by the dissolved  $\text{CO}_2$ . The hardness is "temporary" because the

$\text{CO}_2$  is driven off by boiling, and the soluble bicarbonates are precipitated as insoluble carbonates.<sup>7</sup> The reaction is as follows:

Permanent hardness, on the other hand, is due mainly to sulphates and chlorids of calcium or magnesium. These salts are stable and, therefore, are not precipitated by boiling.

Waters under 4 degrees of hardness may be considered soft, those exceeding 12 degrees hard. Fifty parts per million of calcium sulphate and chlorid of magnesium is usually regarded as excessive. In the lake cities, 100 parts per million is considered satisfactory, yet such a hardness in eastern Atlantic cities would be considered unsatisfactory. Boiler scale is usually due to deposits of sulphates and carbonates of calcium and magnesium.

Rain water is always soft; surface waters vary, but are usually not very hard; ground waters are apt to be hard.

Two conditions must be present to make a ground water hard: first, the material through which the water passes must contain lime or magnesia, and, second, the conditions must be favorable for dissolving it. The latter practically means that  $\text{CO}_2$  must be present.

Waters drawn from limestone regions vary greatly in hardness. Rain water contains but little carbonic acid and, therefore, has little power of dissolving lime. The principal source of the carbonic acid in ground water is from the soil; and comes from the decomposition of organic matter. The hardness of water, therefore, depends more upon the nature of the catchment area than upon the amount of lime in the various materials over which the water flows. Thus, the water supply of Vienna is comparatively soft, notwithstanding that it comes entirely from limestone rocks. The mountainous region which forms the catchment area is barren and sterile, and the water does not get the carbonic acid needed to dissolve the lime. The Winnipeg water drawn from limestone underlying the rich prairies is excessively hard. It is interesting to note that many deep well waters of eastern Massachusetts are comparatively soft, although they contain large amounts of carbonic acid.

**The Clark Method of Softening Water.**—Lime is added to the water either in the form of freshly slaked lime or milk of lime. The calcium hydroxid unites with the carbon dioxid in the water, forming calcium carbonate, which is insoluble, and at the same time precipitates the calcium carbonate held in solution in the water by the  $\text{CO}_2$ . Sodium carbonate is used to reduce the permanent hardness of water due to sulphates.

<sup>7</sup> Calcium carbonate is very slightly soluble in cold water—30 parts per million; magnesium carbonate 880 parts per million.

When bicarbonate of lime or magnesia are precipitated with lime water the following reaction takes place:

(Note: The hardness of water is always expressed in terms of  $\text{CaCO}_3$ , therefore, all calcium and magnesium salts which cause hardness are reduced to terms of  $\text{CaCO}_3$ .)

The amount of lime added is weighed as unslaked lime ( $\text{CaO}$ ), therefore, the molecular weight of slaked lime ( $\text{Ca(OH)}_2$ ) is expressed in terms of  $\text{CaO}$ .)

One grain of  $\text{CaO}$  per gallon = 17.1 parts per million.

$17.1 \times \frac{100}{56} = 31$  parts per million as  $\text{CaCO}_3$ .

Or, 100 parts per million  $\text{CaCO}_3$  will require 3.2 grains per gallon.

$\text{CaO} = 455$  pounds per million gallons.

When sulphates and chlorids of lime and magnesia are precipitated with soda ash, the reactions are:

1 grain of  $\text{Na}_2\text{CO}_3$  per gallon = 17.1 parts per million.

$17.1 \times \frac{100}{106} = 16$  parts per million as  $\text{CaCO}_3$ , but present as  $\text{CaSO}_4$ .

Or, 100 parts per million will require 6.4 grains of  $\text{Na}_2\text{CO}_3$  per gallon = 900 pounds per million gallons.

**Softening Water with a Zeolite-Permutit.**—This is an efficient and automatic method useful for softening water for household or other purposes. Zeolites have the property of exchanging the sodium base which they contain for other bases brought into contact with them. They exist naturally in soils, where they play the important rôle of holding potassium and other alkaline bases in the soil and thus preventing their being washed away with the rain water.

For the purpose of water softening, a *synthetic exchange silicate* (Permutit) is now found upon the market. Synthetic exchange silicates are produced commercially by fusing felspar, kaolin, pearl ash and soda. The glass thus produced is crushed and lixiviated to remove the soluble silicates. In passing water through one of these "exchange silicates," the calcium and magnesium are entirely removed from the water, and exchanged for the sodium of the zeolite. The zeolite can be rejuvenated with a 10 per cent. solution of sodium chlorid. The Permutit process is used to soften water in homes, hotels, laundries, textile and other industries, and to prevent boiler scale.

**Methods.**—The hardness of water, both temporary and permanent, is determined by the soap method. By far the most accurate method of determining the true temporary hardness due to the bicarbonate alkalinity

ity is to titrate the original sample of water, and also some of the water after boiling, with  $\frac{N}{50}$  sulphuric acid, using lacmoid or erythrosin as an indicator, as already described under Reaction, page 1059.

The soap method is carried out as follows: Measure 50 c. c. of the water into a 250-c. c. bottle and add the standard soap solution in small quantities at a time (from 0.2 to 0.3 c. c.), shaking the bottle vigorously after each addition until a lather forms over the entire surface of the water, and remains continuous for 5 minutes after the bottle is laid upon its side. The standard soap solution is made by adding 100 grams of dry white Castile soap to 1 liter of 80 per cent. alcohol; this is standardized against a known calcium chlorid solution. From the amount of soap solution added, the quantity of calcium carbonate equivalent to each cubic centimeter of the soap solution is indicated in the following table:

*Table of hardness, showing the parts per million of calcium carbonate ( $\text{CaCO}_3$ ) for each tenth of a cubic centimeter of soap solution when 50 c. c. of the sample are used*

c. c. of Soap Solution	0.0 c. c.	0.1 c. c.	0.2 c. c.	0.3 c. c.	0.4 c. c.	0.5 c. c.	0.6 c. c.	0.7 c. c.	0.8 c. c.	0.9 c. c.
0.0.....	....	....	....	....	....	....	....	0.0	1.6	3.2
1.0.....	4.8	6.3	7.9	9.5	11.1	12.7	14.3	15.6	16.9	18.2
2.0.....	19.5	20.8	22.1	23.4	24.7	26.0	27.3	28.6	29.9	31.2
3.0.....	32.5	33.8	35.1	36.4	37.7	38.0	40.3	41.6	42.9	44.3
4.0.....	45.7	47.1	48.6	50.0	51.4	52.9	54.3	55.7	57.1	58.6
5.0.....	60.0	61.4	62.9	64.3	65.7	67.1	68.6	70.0	71.4	72.9
6.0.....	74.3	75.7	77.1	78.6	80.0	81.4	82.9	84.3	85.7	87.1
7.0.....	88.6	90.0	91.4	78.6	94.3	95.7	97.1	98.6	100.0	101.5

To translate parts per million to degrees of hardness, use the following table:

*Conversion table of hardness*

Parts	Parts per Million	Clark Degrees	French Degrees	German Degrees
Parts per million.....	1.00	0.07	0.10	0.056
Clark degrees.....	14.3	1.00	1.43	0.80
French degrees.....	10.0	0.70	1.00	0.56
German degrees.....	17.9	1.24	1.78	1.00

English degrees of hardness (Clark's scale) represent grains of calcium carbonate per imperial gallon.

French degrees of hardness represent parts per 100,000 of calcium carbonate.

German degrees of hardness represent parts per 100,000 of calcium oxid.

To convert hardness from one scale to another, multiply by the factor opposite the scale in which it is expressed and under the scale to which it is to be converted. Thus, to convert parts per million to Clark degrees, multiply by 0.07.

The stock soap solution is composed of 100 grams of dry white Castile soap in 1 liter of 80 per cent. alcohol. The solution is standardized against a standard calcium chlorid solution. To make the latter dissolve 0.2 gram pure calcium carbonate in dilute hydrochloric acid, evaporating several times to dryness with distilled water to expel free acid. The residue is diluted to 1 liter. In standardizing, 20 c. c. of the calcium chlorid solution is diluted to 50 c. c. with distilled water, and stock soap solution added as described above. The strength of the latter is then adjusted with 70 per cent. alcohol, so that 6.4 c. c. of it will give a permanent lather to 20 c. c. standard calcium chlorid solution under the conditions outlined. One liter of the resulting standard soap solution usually requires from 75 to 100 c. c. of stock soap solution.

In adding the soap solution to waters containing magnesium salts it is necessary to avoid mistaking the false or magnesium end-point for the true one. If the end-point was due to magnesium the lather now disappears. Soap solution must then be added until the true end-point is reached. Usually the false lather persists for less than 5 minutes. Consequently, after the titration is apparently finished, read the burette and add about 0.5 c. c. of soap solution.

At best the soap method is not a precise test on account of the varying proportions of calcium and magnesium present in different waters. For the determination of hardness, especially in connection with processes for purification and softening, it is advisable to use volumetric or gravimetric methods.

## ORGANIC MATTER

It is not possible to determine the amount of organic matter present in a sample of water by any direct method. As all protein matter contains nitrogen, methods have been devised to determine the total amount of nitrogen and also the amount of nitrogen in various combinations. From such data valuable information concerning the sanitary history and sanitary quality of the water may be inferred. The nitrogen is determined as (1) total nitrogen; (2) nitrogen as free ammonia; (3) nitrogen as albuminoid ammonia; (4) nitrogen as nitrites; (5) nitrogen as nitrates.

The organic matter in water is of animal and vegetable origin and exists both in solution and in suspension. Some of it is in the body of living beings; some of it is in their dead bodies; and some of it is in various stages of decomposition until the final stable compounds, such as ammonia and nitrates, are reached. The total amount of organic matter present in a sample of water is represented by the amount

of nitrogen as free ammonia and albuminoid ammonia. The presence of nitrogen as nitrites and nitrates indicates the amount of self-purification which the water has undergone. Their significance will be discussed separately.

**Free Ammonia.**—If there is much “free” ammonia in the water the sample may be Nesslerized directly. If the water contains comparatively little, as is usually the case; the ammonia must first be concentrated by distillation and condensation.

Place 500 c. c. of the sample of water in a metal or glass still connected to a tin or aluminium condenser in such a way that the distillate may be conveniently delivered directly into Nessler tubes. The entire apparatus must first be freed from ammonia by blowing steam through it until the distillate shows no trace of free ammonia. When this has been done the distilling flask is emptied and 500 c. c. of the sample water measured into it. The distillation should be carried on at a rate so that not more than 10 c. c. nor less than 6 c. c. condense per minute; that is, it should take from 5 to 10 minutes to distill 50 c. c., which is the quantity Nessler tubes are ordinarily graduated to contain. Four Nessler tubes of the distillate containing 50 c. c. each are collected from the first portion that comes over; these contain the free ammonia.

If the sample is acid, or if the presence of urea is suspected, about one-half gram of sodium carbonate should be added previous to distillation, otherwise the ammonia will not come off. Sodium carbonate is omitted, when possible, as it tends to increase “bumping.”

The amount of ammonia is determined by adding 2 c. c. of Nessler reagent to each tube and comparing the depth of color with a set of standard tubes prepared with a known quantity of ammonium chlorid solution, plus an equal quantity of Nessler reagent.

*Nessler's reagent* is prepared by dissolving 50 grams of potassium iodid in a minimum quantity of cold water. To this add a saturated solution of mercuric chlorid until a slight permanent precipitate persists. Then add 400 c. c. of 50 per cent. potassium hydroxid solution which has been allowed to clarify by sedimentation before using; dilute to one liter, allow to stand, and decant.<sup>8</sup> The solution should give the required color with ammonia within 5 minutes after addition, and should not precipitate with small amounts of ammonia within 2 hours. The reaction between Nessler's reagent and ammonia is an empiric one. The  $\text{HgI}_2\text{KIKOH}$ , which constitutes the Nessler's reagent in the presence of ammonia, forms a brownish compound which is known as mercurammonium iodid, and has the formula  $\text{NHg}_2\text{IH}_2\text{O}$ .

<sup>8</sup> Another method of making Nessler's reagent will be found in Sutton's “Volumetric Analysis.”

Ammonia-free water may readily be obtained by distilling water containing about 0.2 per cent. dilute sulphuric acid.

*Standard  $\text{NH}_4\text{Cl}$  Solution.*—The standards for comparison consist of ammonium chlorid dissolved in ammonia-free water. Dissolve 3.82 grams of ammonium chlorid in 1 liter of water; dilute 10 c. c. of this to 1 liter with the ammonia-free water. One c. c. will then equal 0.00001 gram of nitrogen as ammonia.

A gram molecule of  $\text{NH}_4\text{Cl}$  weighs 53.5 grams—that is:

$$\text{N } 14 + \text{H } 4 + \text{Cl } 35.5 = 53.5$$

The equation would then be:

$$\begin{aligned} 14 : 53.5 &:: 1 : x \\ x &= 3.82 \end{aligned}$$

That is, if there are 14 grams of nitrogen in 53.5 grams of ammonium chlorid, then 1 gram of nitrogen is contained in 3.82 grams of ammonium chlorid. It is to be noted that, while the method determines the amount of ammonia, the results are expressed in terms of nitrogen. In the same way the nitrites and nitrates are also expressed in terms of nitrogen.

Prepare a series of 16 Nessler tubes, which contain the following number of cubic centimeters of the standard ammonium chlorid solution, namely: 0.0, 0.1, 0.3, 0.5, 0.7, 1.0, 1.4, 1.7, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, and 6.0; dilute each one to the 50 c. c. mark with ammonia-free water. These will contain 0.00001 gram of nitrogen for each cubic centimeter of the standard solution used. Add about 1 c. c. of the Nessler reagent to each tube; do not stir the contents of the tubes.

The color produced in the distillate from the sample under examination is now compared with standards by looking vertically downward through them at a white surface placed at an angle in front of a window so as to reflect the light upward. The tubes should be allowed to stand at least 10 minutes after Nesslerizing before making the comparison.

The last 50 cubic centimeters of the distillate examined should contain no ammonia, or at most a trace, otherwise it may be inferred that all has not been collected, or some error has crept into the work. It is not uncommon for the last tube to contain a little ammonia when the organic matter is of plant origin. Ammonia determinations should be carried out in a special room, where at least volatile ammonia reagents are not exposed. Special care must be exercised not to contaminate the Nessler tubes with soiled fingers, rags, etc. Care must be exercised thoroughly to wash the tubes free from alkaline soaps, and to rinse with ammonia-free water. The Nessler tubes containing the standard

solution and the samples for comparison should be at the same temperature, and other conditions should be as nearly alike as possible.

*Example.*—

The first Nessler tube=2.5 c. c. standard  $\text{NH}_4\text{Cl}$  solution, or 0.000,025 gram N as  $\text{NH}_3$ .

The second Nessler tube=0.7 c. c. standard  $\text{NH}_4\text{Cl}$  solution, or 0.000,007 gram N as  $\text{NH}_3$ .

The third Nessler tube=0.0 c. c. standard  $\text{NH}_4\text{Cl}$  solution, or 0.000,000 gram N as  $\text{NH}_3$ .

Total, 0.000,032 gram N as  $\text{NH}_3$ .

(Note: 1 c. c. of the standard solution contains 0.00001 gram of N as  $\text{NH}_3$ .)

Only 500 c. c. of the sample of water was distilled. We must, therefore, multiply by 2 in order to obtain the amount of N in one liter:

$$0.000,032 \times 2 = 0.000,064 \text{ gram of N as } \text{NH}_3 \text{ per 1,000 c. c.}$$

If 1,000 c. c. contains 0.000,064 gram of N as  $\text{NH}_3$ , 1,000,000 parts will contain 0.064 part of N as  $\text{NH}_3$ —usually expressed as 0.064 part per million.

A simpler method of making the calculation is as follows.

First Nessler tube..... 2.5

Second Nessler tube..... 0.7

Third Nessler tube..... 0.0

---

$$3.2 \times 0.02 = 0.064 \text{ part per million.}$$

*Significance of Free Ammonia.*—The free ammonia which comes off with the first part of the distillate usually exists in the water as chlorids or carbonates. It is called “free ammonia” because these salts are readily decomposed and the ammonia is expelled by boiling.

Rain water washes down some free ammonia which is found in the atmosphere. Angus Smith and Boussingault place the average amount of ammonia in the rain of temperate climates as 0.5 part per million.

The amount of ammonia in rain water was studied by Filhol. He found that in the city of Toulouse the rain water contained 6.60 parts per million, while the rain water collected near the city contained only from 0.44 to 0.77 part per million. These figures show the marked difference between city and country rain.

In a surface or ground water free ammonia represents one of the latter stages of putrefaction of organic matter; thus, the bacterial decomposition of sewage yields ammonia in abundance.

The ammonia itself ordinarily found in drinking water is harmless; its significance lies in the fact that it indicates the presence of putrefying organic matter.

The presence of free ammonia in clean and properly stored rain water has much less significance than in a surface or ground water.

Free ammonia in water results not only from the decomposition of nitrogenous organic matter, but is also formed during the process of denitrification, by which nitrates are again reduced to nitrites and nitrites to ammonia. This action only takes place near the surface of the soil, and to a limited extent. Deep well waters of exceptional purity upon chemical analysis and practically sterile upon bacteriological examination, may contain a relatively high percentage of free ammonia. This is supposed to come from a chemical reduction under high pressure and perhaps temperature of the geological nitrogenous matter in coal and alluvial deposits.

A definite permissible limit for the amount of free ammonia which good water should contain cannot be fixed. Its significance must be judged from the other constituents of the water and a sanitary survey of its source. As a rule, safe water may contain from 0.015 to 0.03 or even 0.055 part per million. In general, free ammonia is less of a danger signal than the fixed or albuminoid ammonia.

**Albuminoid Ammonia.**—Nitrogen as albuminoid ammonia is always determined in conjunction with and as a continuation of the method for determining nitrogen as free ammonia. After obtaining 200 c. c. (that is, 4 Nessler tubes of 50 c. c. each) from the first portion of the distillate, for the purpose of determining nitrogen as free ammonia, withdraw the flame, disconnect the flask and add 40 c. c. or more of hot alkaline potassium permanganate, and continue the distillation until at least 4 portions of 50 c. c. each, or, preferably, 5 portions, of the distillate have been collected in separate Nessler tubes.

The calculation is as follows:

First Nessler tube.....	1.7
Second Nessler tube.....	0.8
Third Nessler tube.....	0.5
Fourth Nessler tube.....	0.3
Fifth Nessler tube.....	0.3

---

$$3.6 \times 0.02 = 0.072 \text{ part per million.}$$

The alkaline potassium permanganate solution is made by pouring 1,200 c. c. of distilled water into a porcelain dish holding 2,500 c. c.; boil 10 minutes and turn off the gas. Add 16 grams of C. P. potassium permanganate and stir until dissolved. Then add 800 c. c. of 50 per cent. clarified solution of potassium or sodium hydrate and enough distilled water to fill the dish. Boil down to 2,000 c. c. Test each batch of this solution for albuminoid ammonia by making a blank determination. Correction should be made accordingly.

After the readily decomposed ammonia salts have been broken up and the ammonia driven off in the steam which condenses to form the first 200 c. c., the remainder of the sample of water in the still contains nitrogenous organic matter that requires a strong oxidizing agent to disintegrate it. This is accomplished by the alkaline potassium permanganate. The nitrogen in the complex protein molecule finally forms ammonia, and hence this is called albuminoid ammonia; the amount of it is determined by Nesslerization, precisely as for free ammonia. In ground waters and surface waters containing but little pollution the nitrogen as albuminoid ammonia usually approximates about one-half of the total organic nitrogen. In sewage and other liquids containing considerable nitrogenous organic matter the percentage of ammonia forming organic matter is variable. For this reason the amount of albuminoid ammonia obtained by the alkaline permanganate method is less valuable than the total organic nitrogen determined by the Kjeldahl method.

If it is desired to determine how much of the organic matter is in solution and how much in suspension, the sample of water should be passed through a Berkefeld filter. The albuminoid ammonia in the filtrate represents the dissolved organic matter, and the difference between the albuminoid ammonia in the total sample and the filtered sample gives the suspended nitrogen as albuminoid ammonia.

The albuminoid ammonia is a fairly correct index of the amount of organic pollution in the water. It comes from minute organisms, both living and dead, that are in the sample, also from particles of animal and vegetable matter in suspension, and finally from the nitrogenous substances in solution and in various stages of decomposition. The organic matter in itself is not dangerous to health, but is undesirable because it putrefies and thus gives a water disagreeable tastes and odors; further, it offers food for bacterial growth. The amount of albuminoid ammonia is therefore an index of pollution, but if of vegetable origin it has much less sanitary significance than if of animal origin. Organic matter of animal origin yields a much larger amount of albuminoid ammonia than a similar amount of vegetable matter. Whether the organic matter comes from sewage, from a dead carcass, or from the swamps, cannot be stated with certainty from this test, but if the albuminoid ammonia comes over quickly, that is, if most of it appears in the first Nessler tube, it is presumably of animal origin; whereas, if the ammonia comes over more slowly and the second and third Nessler tubes contain appreciable amounts, the organic matter is presumably of vegetable origin.

No arbitrary standard can be set as to the maximum amount of albuminoid ammonia a good water may contain. Waters considered

"pure" often contain as much as 0.079 to 0.34 part of nitrogen as albuminoid ammonia per million.

**Nitrites.**—Nitrites in water are regarded as a special danger signal. The reason for this is that nitrites indicate that active putrefaction of nitrogenous organic matter is going on as the result of bacterial activity. The presence of nitrites, therefore, at once suggests organic pollution. The presence of nitrites in water represents the transitional stage in the oxidation of organic matter between ammonia and nitrates, and therefore indicates incomplete oxidation of the protein and the active growth of bacteria.

Nitrites are never present except in small amounts, for they are soon oxidized to the higher and more stable nitrates, but a minute amount, according to some authorities, is sufficient to condemn a water. As a rule, pure water contains no nitrites, or traces only; on the other hand, nitrites may be absent from an impure water, owing to the fact that the oxidation has not reached this stage, or perhaps has entirely passed it. The absence of nitrites, therefore, does not mean that the water is necessarily safe, while their presence in any but the smallest measurable amounts shows pollution. We must not give to the nitrites an exaggerated importance: they are a danger signal in the same sense that the colon bacillus is a danger signal, indicating pollution but not necessarily infection, for they do not tell the source or nature of the organic matter. The presence of nitrites in spring and deep well water may be without sanitary significance, for in these cases they may be generated by the deoxidation of the nitrates which is brought about either by the action of reducing substances, such as ferrous oxid, or by organic matter. It should be remembered that the colorimetric test for nitrites with sulphanilic acid and  $\alpha$ -amidonaphthylamin is one of the most delicate tests in chemistry. With this method we are able to detect quantities as small as one part in a hundred million. When, therefore, a water analyst reports a trace of nitrites it means an exceedingly minute quantity.

Nitrites are not only formed by the nitrifying bacteria in the soil from ammonia, but are also formed from the denitrification of nitrates by a variety of microorganisms. The typhoid bacillus, the colon bacillus, and many other bacteria have the power of producing nitrites in culture media.

Nitrites are poisonous, but the minute amounts found in water can scarcely have a pharmacological effect.

**Method for Estimating Nitrogen as Nitrites**—*Reagents:* (1) *Sulphanilic acid solution.* Dissolve eight grams of the purest sulphanilic acid in 1,000 c. c. of 5 N. acetic acid (sp. gr. 1.041). This is practically a saturated solution.

(2) *Naphthylamin acetate or chlorid solution.* Dissolve 5.0 grams

solid  $\alpha$ -naphthylamin in 1,000 c. c. of 5 N. acetic acid; filter the solution through washed absorbent cotton, or an alundum filter.

(3) *Sodium nitrite, stock solution.* Dissolve 1.1 grams silver nitrite in nitrite-free water; precipitate the silver with sodium chlorid solution and dilute the whole to one liter.

(4) *Standard sodium nitrite solution.* Dilute 100 c. c. of solution (3) to one liter; then dilute 5 c. c. of this solution to one liter with sterilized nitrite-free water; add one c. c. of chloroform and preserve in a sterilized bottle. One c. c. = 0.0005 mg. nitrogen.

*Procedure.*—Measure out 50 c. c. of the decolorized sample (decolorized by adding aluminium hydrate free of nitrite—see under Chlorin), or a smaller portion diluted to 50 c. c., into a Nessler tube. At the same time make a set of standards by diluting various volumes of the standard nitrite solution in Nessler tubes to 50 c. c. with nitrite-free water, for example, 0.0, 0.1, 0.2, 0.4, 0.7, 1.0, 1.4, 1.7, 2.0, and 2.5 c. c. Add 1 c. c. each of reagents Nos. 1 and 2 (above) to each 100 c. c. of the sample and to each standard. Mix; allow to stand 10 minutes. Compare the samples with the standards. Do not allow the samples to stand over one-half hour before being compared, on account of absorption of nitrites from the air. Make a blank determination in all cases to correct for the presence of nitrites in the air, the water and other reagents. Dilute all samples which develop more color than the 2.5 c. c. standard before comparing. Mixing is important.

When 50 c. c. of the sample are used, then 0.01 times the number of c. c. of the standard gives the parts per million of nitrogen as nitrite.

*Calculation.*—One c. c. of the standard equals 0.0005 mg. N. as nitrites. 50 c. c. of the sample is used and is found to equal 0.5 c. c. of the standard.

Then 50 c. c. sample contains 0.00025 mg. N. as nitrites and one liter will contain  $20 \times 0.00025$  or 0.005 mg. of N. or 0.005 part per million.

When 50 c. c. of the sample is used  $20 \times 0.0005 \times$  the number c. c. of the standard will give the number mg. N. per liter or parts per million. This can be shortened to  $0.01 \times$  the number c. c. standard used equal parts per million of N. as nitrites.

**Nitrates.**—Nitrates are the end products of the mineralization of organic matter. Their presence, therefore, signifies past or distant pollution. While the absence of nitrates does not necessarily mean purity, their presence, on the other hand, does not necessarily indicate immediate danger. If a water contains an appreciable quantity of nitrates and no nitrites, it shows that the source of pollution has been distant and that the organic matter has been completely oxidized. In waters considered pure the nitrates are rarely less than 0.3 part, or they may run as high as 1.6 parts, per million. Polluted waters usually

contain very much more, as 17 to 20, or more parts per million. Nitrates usually exist in water as salts of alkaline bases.

Young<sup>a</sup> has shown that the ground waters of Kansas sometimes contain large amounts of nitrates—as much as 500 parts per million. The medicinal dose of potassium nitrate is 0.3 gram. Less than a liter of water would therefore contain sufficient nitrates to produce therapeutic effects such as irritation of the mucous membrane of the stomach, resulting in gastritis, and also diuresis, with irritation of the mucous membrane of the bladder.

The test for nitrates depends upon the fact that they react with phenoldisulphonic acid to form a compound resembling picric acid, which is yellow in the presence of an alkali. The amount of nitrates is determined colorimetrically by comparison with standard solutions.

**Phenoldisulphonic Acid Method.**—*Reagents:* (1) *Phenoldisulphonic acid.* Dissolve 25 grams of pure white phenol in 150 c. c. of pure concentrated sulphuric acid. Add 75 c. c. of fuming sulphuric acid (15 per cent.  $\text{SO}_3$ ), stir well, and heat for 2 hours at about  $100^\circ \text{C}$ .

(2) *Potassium hydroxid solution.* Prepare an approximately 12 N. solution, 10 c. c. of which will neutralize about 4 c. c. of the phenoldisulphonic acid.

(3) *Standard nitrate solution.* Dissolve 0.72 gram of pure recrystallized potassium nitrate in 1 liter of distilled water. Evaporate cautiously to dryness 10 c. c. of the solution on the water bath. Moisten residue quickly and thoroughly with 2 c. c. of phenoldisulphonic acid and dilute to 1 liter. This is the standard solution, 1 c. c. of which equals 0.001 mg. of nitrate nitrogen.

(4) *Standard silver sulphate solution.* Dissolve 4.4 grams of silver sulphate free from nitrate in 1 liter of water. One c. c. of this solution is equal to 1 mg. of chlorid.

*Procedure.*—The alkalinity, chlorid and nitrite content, and color of the sample must first be determined. If the sample is highly colored decolorize it with freshly precipitated aluminium hydroxid. Measure into an evaporating dish 100 c. c. of the sample, or if nitrate is very high such volume as will contain about 0.01 mg. of nitrate nitrogen. Add sufficient  $\frac{\text{N}}{50}$  sulphuric acid nearly to neutralize the alkalinity. Then add sufficient standard silver sulphate to precipitate all but about 0.1 mg. of chlorid. The removal of chlorid may be omitted if the sample contains less than 30 parts per million of chlorid. Heat the mixture to boiling, add a little aluminium hydroxid, stir, filter, and wash with small amounts of hot water. Evaporate the filtrate to dryness, and add 2 c. c. of the phenoldisulphonic acid, rubbing with a glass rod to insure intimate contact. If the residue becomes packed or appears vitreous because of the presence of much iron, heat the dish on the water bath for

<sup>a</sup>Young, C. C.: *Jour. A. M. A.*, June 24, 1911, LVI, p. 1881.

a few minutes. Dilute the mixture with distilled water, and add slowly a strong solution of potassium hydroxid or ammonium hydroxid until the maximum color is developed. Transfer the solution to a Nessler tube, filtering if necessary. If nitrate is present a yellow color will be formed. Compare the color with that of standards made by adding 2 c. c. of strong potassium hydroxid or ammonium hydroxid to various amounts of standard nitrate solution and diluting them to 50 c. c. in Nessler tubes. The following amounts of standard nitrate solution are suggested: 0, 0.5, 1.0, 1.5, 2.0, 4.0, 6.0, 8.0, 10.0, 15.0, 20.0, and 40.0 c. c. These standards may be kept several weeks without deterioration. If 100 c. c. of water is used the number of cubic centimeters of the standard multiplied by 0.01 is equal to parts per million of nitrate nitrogen.

Standards that will remain permanent for several years if stored in the dark may be prepared from tripotassium nitrophenoldisulphonate.

If nitrate nitrogen is present in excess of 1 part per million it should be oxidized by heating the samples a few minutes with a few drops of hydrogen peroxid, free from nitrate, repeatedly added, or by adding dilute potassium permanganate in the cold until a faint pink coloration appears; the nitrogen equivalent of the nitrite thus oxidized to nitrate is then subtracted from the final nitrate nitrogen reading.

## CHLORIDS

Chlorin as sodium chlorid or common salt is a normal constituent of all waters. Traces of it taken up from the air are found in rain water, especially near the seacoast. The rain water collected at Troy, New York, was found by Mason to average 1.64 parts per million of chlorin. The amounts varied from 0.75 part per million in April to 3 parts per million in October. The chlorid in surface and ground waters, generally speaking, comes from the mineral deposits in the earth; from the ocean vapors and spray carried inland by the wind; also from polluting materials like sewage and trade wastes, both of which are apt to contain the common salt used in the household and in manufacturing. A comparison of the chlorin content of a water with that of other waters in the general vicinity known to be unpolluted frequently affords useful information as to its sanitary quality.

Before the water analyst is able properly to interpret the significance of the chlorin content of a water it is necessary to know the normal amount of chlorin present in the waters of that locality. Thus, surface waters near Provincetown, on Cape Cod, contain from 23 to 24 parts of chlorin per million, while surface waters near Boston contain from 3 to 6 parts per million. Near the middle of the state of Massachusetts

(Worcester) the surface waters contain only 1.2 to 1.9 parts per million, while in the western portion of the state, farthest from the sea, the surface waters contain but 0.7 to 0.9 part per million. The amount of normal chlorid in the waters of Massachusetts has been carefully studied by the State Board of Health, and a map has been issued showing the isochlors, or normal chlorin lines.

In Massachusetts the whole of the surface of the country, with the exception of a very small portion, is non-calcareous, and the surface waters carry but little chlorin in composition, if unpolluted, the amount of chlorin decreasing continuously from the coast inland. In a report on the State water supplies, 1887-1890, the Commissioners state that "in a general way 4 families or 20 persons per square mile will add, on an average, 0.01 of a part per 100,000 of chlorid (0.1 part per million) to the water flowing from this area, and that a much smaller population will have the same effect during seasons of low flow."

The amount of chlorid in a water of a district varies with several factors, such as the distance from the sea, the amount of rainfall, the amount of evaporation, and the direction of the winds. An increase over the normal is an indication of pollution, and comes mostly from urine. While the ammonia and the nitrites may have disappeared and the nitrates may have been largely taken up by growing vegetation, the chlorid salts, which are exceedingly stable, will be left to indicate remote or passed pollution.

The mixture of even a small proportion of sea-water renders the water hard and salty and undesirable for domestic use. Magnesium chlorid also renders a water unsuitable for use in boilers. Wells driven near the sea frequently become mixed with sea-water, particularly if sufficient water is withdrawn to cause suction. When this happens the sea-water passes back under the wells as an undercurrent and gradually mixes with the fresh water above it and sooner or later appears in the well. When this happens it may be a slow and hard process to operate the well so as to avoid drawing sea-water. In wells near the sea it is important to draw no more fresh water than would otherwise flow to the ocean. This is often a difficult problem to arrange so as to get the maximum quantity of water obtainable. This sea-water question has been more thoroughly and scientifically studied in Holland than elsewhere.

**Determination of Chlorid—Reagents:** (1) *Standard salt solution.* Dissolve 16.48 grams of fused sodium chlorid in one liter of distilled water. Dilute 100 c. c. of this stock solution to one liter in order to obtain a standard solution, each c. c. of which contains 0.001 gram of chlorid.

(2) *Silver nitrate solution.* Dissolve about 2.40 grams of silver nitrate crystals in one liter of distilled water. One c. c. of this will

approximately equal 0.0005 gram of chlorid. Standardize this against the standard salt solution.

(3) *Potassium chromate*. Dissolve 50 grams of neutral potassium chromate in a little distilled water. Add enough silver nitrate to produce a slight red precipitate. Filter and make up the filtrate to one liter with distilled water.

(4) *Aluminium hydroxid*. This is used only to clarify the water in case of high color. Dissolve 125 grams of potash or ammonium alum in one liter of distilled water. Precipitate the aluminium hydrate by cautiously adding ammonium hydroxid. Wash the precipitate in a large jar by the successive addition of distilled water and by decantation until free from chlorid, nitrite, and ammonia.

*Procedure*.—For this determination where the chlorid content is not extremely low or very high, titrate 50 c. c. of the sample in a white six-inch porcelain evaporating dish with the standard silver nitrate solution. If the chlorid is very high in amount, use 25 c. c., or even a smaller quantity if desired, diluting the volume taken with distilled water to 50 c. c. When the sample is very low in its chlorid content, more accurate results may be obtained by using 50 c. c. of the sample and adding, prior to titration, 1 c. c. of standard salt solution.

Measure out 50 c. c. of the sample into the evaporating dish. Into another, measure 50 c. c. of distilled water. Add to each, 1 c. c. of the potassium chromate indicator. To the sample add carefully from the buret, standard  $\text{AgNO}_3$  until the red of the silver chromate persists, using the distilled water for comparison of colors. Record number of c. c. of the standard  $\text{AgNO}_3$  solution used.

*Calculation*.—One c. c. of the silver nitrate solution equals 0.0005 gm. of chlorid.

Assuming that 50 c. c. of the sample requires 5 c. c. of the standard, then 50 c. c. of the sample contains  $0.0005 \times 5 = 0.0025$  gm. of Cl. or 2.5 mg. of Cl.

1,000 c. c. then would contain  $2.5 \times 20$  or 50 mg. Cl.; or 50 parts per million.

In short, when the standard silver solution equals just 0.0005 gm. Cl., the number of c. c. used in titrating multiplied by 10 will give the parts per million.

## CHLORIN

In waters that have been treated with calcium hypochlorite or liquid chlorin, it is frequently advisable to ascertain the presence or absence of chlorin. As the reagents which have been proposed for its detection are not specific for chlorin but give similar or identical reactions with oxidizing agents or reducible substances care must be exercised in

interpreting the results of such tests: nitrites and ferric salts are of common occurrence, and chlorates also may lead to misinterpretation in waters treated with calcium hypochlorite.

*Reagents:* (1) *Tolidin solution.* One gram of o-tolidin, purified by being recrystallized from alcohol, is dissolved in 1 liter of 10 per cent. hydrochloric acid.

(2) *Copper sulphate solution.* Dissolve 1.5 grams of copper sulphate and 1 c. c. of concentrated sulphuric acid in distilled water and dilute the solution to 100 c. c.

(3) *Potassium bichromate solution.* Dissolve 0.025 gram of potassium bichromate and 0.1 c. c. of concentrated sulphuric acid in distilled water and dilute the solution to 100 c. c.

*Procedure.*—Mix 1 c. c. of the tolidin reagent with 100 c. c. of the sample in a Nessler tube and allow the solution to stand at least 5 minutes. Small amounts of free chlorine give a yellow and larger amounts an orange color.

For quantitative determination compare the color with that of standards in similar tubes prepared from the solutions of copper sulphate and potassium bichromate. The amounts of solution for various standards are indicated in the following table:

PREPARATION OF PERMANENT STANDARDS FOR CONTENT OF CHLORIN

Chlorin	Solution of Copper Sulphate	Solution of Potassium Bichromate
<i>Parts per Million</i>	<i>c. c.</i>	<i>c. c.</i>
0.01	0.0	0.8
.02	.0	2.1
.03	.0	3.2
.04	.0	4.3
.05	.4	5.5
.06	.8	6.6
.07	1.2	7.5
.08	1.5	8.7
.09	1.7	9.0
.10	1.8	10.0
.20	1.9	20.0
.30	1.9	30.0
.40	2.0	38.0
.50	2.0	45.0

## OXYGEN

**Oxygen Consumed.**—The oxygen consumed means the oxygen which the organic compounds in water consume when treated in an acid solution with potassium permanganate. The expression is synonymous with “oxygen required” or “oxygen absorbed.” Oxygen consumed is, therefore, an index of the amount of putrescible organic matter present and should carefully be distinguished from the expression “dissolved oxy-

gen," which refers simply to the amount of oxygen held in solution by the water.

It is the carbon and not the nitrogen in organic matter which is oxidized by potassium permanganate in an acid solution; hence this determination is frequently referred to as an indication of the carbonaceous organic matter present. The method indicates only a certain portion of the carbon, and this ratio varies in different samples of water. Further, it does not differentiate the carbon present in unstable organic matter from that in what might be called fairly stable organic matter, such as is sometimes referred to as "residual humus." The presence of nitrites, ferrous iron, sulphids, or other unoxidized mineral compounds causes oxygen to be taken up and hence increases the amount of oxygen consumed by this method. In case such substances are present, a correction should be made when studying carbonaceous organic matter.

**Determination of Oxygen Consumed**—*Reagents:* (1) *Dilute sulphuric acid.* One part of sulphuric acid to three parts of distilled water. This shall be freed from oxidizable matters by adding potassium permanganate until a faint pink color persists after standing several hours.

(2) *Standard ammonium oxalate.* Dissolve 0.888 gram of the pure salt in 1 liter of distilled water. One c. c. is equivalent to 0.1 mg. of oxygen. An equivalent quantity of oxalic acid or sodium oxalate may be used.

(3) *Standard potassium permanganate.* Dissolve 0.4 gram of the crystallized salt in 1 liter of distilled water. Add 10 c. c. of the dilute sulphuric acid and 10 c. c. of this solution of potassium permanganate to 100 c. c. of distilled water, and digest 30 minutes. Add 10 c. c. of the ammonium oxalate solution, and then add potassium permanganate till a pink coloration appears. This destroys the oxygen-consuming capacity of the water used. Now add another 10 c. c. of ammonium oxalate solution and titrate with potassium permanganate. Adjust the potassium permanganate solution so that 1 c. c. is equivalent to 1 c. c. of ammonium oxalate solution or 0.1 mg. of available oxygen. Measure into a flask 100 c. c. of the water, or a smaller diluted portion if the water is of high organic content. Add 10 c. c. of sulphuric acid solution and 10 c. c. of potassium permanganate solution, and allow the treated sample of water to digest exactly 30 minutes at boiling temperature in a water bath of boiling water, the level of which is kept above that of the contents of the flask. Thirty minutes is an arbitrary time.

Precisely at the end of the period of digestion remove the flask and add 10 c. c. of the ammonium oxalate solution. Titrate with the permanganate solution until a faint but distinct color is obtained.

If 100 c. c. of water is used, the number of c. c. of potassium permanganate solution in excess of the number of c. c. of ammonium oxalate solution is equal to parts per million of oxygen consumed.

Should the volume of permanganate solution be insufficient for complete oxidation, repeat the analysis, using a larger volume, so that at least 5 c. c. of the permanganate solution will be present in excess when the ammonium oxalate solution is added.

When unoxidized mineral substances, such as ferrous sulphate, sulphids, nitrites, etc., are present in the sample, corrections should be applied as accurately as possible by procedures suitable for the samples being analyzed. Direct titration of the acidified sample in the cold, using a three-minute period of digestion, serves this purpose quite well for polluted surface waters and fairly well for purified sewage effluents. Raw sewages containing no trade wastes seldom need such a correction, but when raw sewages contain "pickling liquors" it is important. In all samples containing both unoxidized mineral compounds and gaseous organic substances the latter should be driven off by heat and the sample allowed to cool before applying this test for the correction factor. Where such corrections are necessary the fact should be stated, with the amount of correction.

This is one of the oldest methods for determining organic matter and has been in very wide use for more than half a century. It was introduced as soon as the fact was recognized that the loss on ignition of the residue upon evaporation may indicate certain volatile mineral matters, as well as organic matter. To-day the method of determination of oxygen consumed is ordinarily not included in a water analysis for the reason that the results vary widely, depending on the procedure as to certain details of the method, and from the further fact that the determinations of the organic matter in water may be more conveniently and satisfactorily estimated from the free and albuminoid ammonia.

**Dissolved Oxygen.**—Dissolved oxygen is another expression for the degree of aëration or oxygenation of water. It varies from zero to saturation or slight supersaturation. The amount of oxygen in solution is fairly constant in waters of uniform composition freely exposed to the air. Water containing sewage and other oxidizable matters uses up the dissolved oxygen. In badly polluted streams so much of the dissolved oxygen may be lost in this way that fish cannot breathe. They die from suffocation rather than from the toxic effects of the sewage; fish must have at least 2.5 parts of oxygen per million. Water may contain practically no oxygen at depth of 40 or 50 feet, but deep soundings show that aëration probably exists to greater depths, for fish and aërobic organisms live at the bottom of the sea. In this case the oxygen may possibly be obtained from sources other than the dissolved oxygen from the air.

Dissolved oxygen makes water sparkling and palatable and also helps to consume the organic matter. Its absence permits the growth of anaërobic organisms that cause putrefaction and impart putrid tastes and odors to the water. Pasteur's original conception of fermentation was decomposition in the absence of oxygen.

The amount of oxygen found in the water of a running stream taken at different points may furnish valuable information as to the rapidity with which the process of self-purification is taking place from a chemical standpoint.

The amount of oxygen dissolved in a water may be measured by three methods, viz., that of Winkler, Thresh, or Levy. The method of Winkler is generally used in this country and possesses the advantage of requiring only simple and not readily breakable apparatus. It is therefore recommended as the standard method.

**Sample.**—To determine the amount of dissolved oxygen it is necessary to collect the sample with extreme care in order to avoid the entrainment of any oxygen from the atmosphere. The sample bottles should be glass-stoppered, with a narrow neck, holding at least 250 c. c. The exact capacity of the bottle must be determined. The bottle should be filled through a glass or rubber tube which reaches to the bottom of the bottle, and the water allowed to overflow for several minutes, after which the glass stopper is carefully replaced, so that no bubble of air is caught beneath it.

## IRON

Iron in water influences its quality from the standpoint of desirability rather than from the standpoint of health. After hardness there is no question of greater practical importance in considering the quality of a water. All natural waters contain a certain amount of iron, and ground waters are apt to contain it in objectionable amounts. No water can be considered entirely satisfactory that contains more than about 1 part of total iron per million parts of water. Appreciable amounts of iron render water unsuitable for domestic and technical purposes; it stains clothes in the laundry, but has little sanitary significance, for when present in large amounts, its undesirable taste would preclude its use.

When iron is present in water it supports a fungus (*Crenothrix kuehniana*), an organism which may grow in the pipes in sufficient amount to obstruct the flow of water or even completely choke the pipe. It is chiefly troublesome in ground waters containing organic matter and iron. This was the cause of the complete obstruction of the water pipes in the New York Custom House in 1907. The same sometimes occurs in the pipes of driven wells.

Iron is very widely distributed and exists in practically all sands, gravels, soils, and rocks with which water comes in contact. The solution of the iron is brought about by the organic matter. The iron exists in the soil as ferric compounds. These are reduced by the organic matter to ferrous salts, which are soluble in water containing carbonic acid. Trouble from iron is always to be expected when there is an excess of organic matter in the material through which the water passes. In a well-drained, porous soil the oxygen from the air circulates in the pores of the soil and furnishes what is required for the oxidation of the organic matter. Iron is not dissolved under these conditions, even in the presence of large amounts of organic matter, but if the air supply is cut off, as for instance in case the pores of the soil are filled with water, the solution of iron is sure to take place. The iron is dissolved in the form of ferrous salts, usually ferrous carbonate. When ground waters containing iron are first drawn they look clear, but the ferrous salts in solution are soon oxidized on contact with the air to insoluble ferric salts, which are precipitated as red oxids.

**Iron Pipes.**—Nearly all waters attack iron pipes, corroding them and forming tubercles on the inner surface. This is objectionable, because it reduces the carrying capacity of the pipe and also influences the quality of the water.

Tubercles are formed as follows: The organic matter in the water settles in the pipe and attacks the iron through a blow hole or other minute opening in the coating. The organic matter decomposes, forming carbon dioxid, which acts upon the iron, causing some of it to go into solution as ferrous carbonate. The soluble ferrous carbonate for the most part passes on in the flowing water, but some of it becomes oxidized by the oxygen in the flowing water and is precipitated as the insoluble ferric carbonate and remains at the surface of the deposit. The iron precipitated in this way acts as a coagulant upon the organic matter in the flowing water at the point where the iron is precipitated. It thus attracts the organic matter from the flowing water and binds it to that previously deposited into a firm, compact, but porous mass, and this mass is the beginning of a tubercle. The process is continuous, though slow. Many years may elapse before the tubercle reaches the height of an inch. Tuberculation starts more freely and progresses more rapidly in waters from rivers or reservoirs containing suspended organic matter. It is less troublesome with filtered waters, and with lake waters relatively free from such suspended matter. Tuberculation may be prevented by improving the quality of the water or by thoroughly coating the inside of the pipes with asphaltum or tar. Cement-lined pipes are not subject to tuberculation, but have defects in other particulars. When the process has advanced far it may be corrected by pipe scrapers. They consist of appliances driven by the water pressure

through the pipes, with arrangements to scrape off the tubercles. This temporarily restores the original carrying capacity of the pipe, but the process must be repeated at intervals. It has the disadvantage of also scraping off a large part of the tar coating and leaving the iron of the pipe exposed to the action of water to a much greater extent. (Hazen.)

Water that passes through the water-backs of the kitchen stove to the hot-water tank is particularly likely to collect iron, which accumulates at the bottom of the hot-water tank. This deposit may accumulate for days and even weeks until some unusual draught of water or other disturbance occurs—perhaps on washing day—causing a stirring up of the iron precipitate. When this happens it is very objectionable.

The household filter is the most convenient and satisfactory means of removing iron deposits from water that is otherwise good. The removal of iron from a city's water supply is a distinct process rarely combined with purification. In most cases iron may be removed by thoroughly aerating the water in order to drive off the excess of  $\text{CO}_2$  and in order to introduce oxygen necessary to oxidize the iron from the soluble ferrous state, in which it exists, to the insoluble ferric state. The precipitated ferric salts can then be removed by sedimentation or, better, by filtration.

## LEAD

**Tests.**—The presence of lead may be discovered by chemical tests or surmised from the symptoms of lead poisoning among those who use the water. In the amounts present it does not affect either the appearance or taste of the water.

It is possible to determine the presence of lead in clear water and roughly estimate its amounts by acidifying with acetic acid, saturating with hydrogen sulphid and comparing the brown tint produced with that produced by standard lead solutions contained in Nessler tubes similar to those for containing the sample under examination. This method is not applicable if the water is colored or contains iron—in this case special analytical procedures are necessary.

The sample of water used for testing lead should be the first portion (a pint or less) drawn after standing at least one hour in the pipes.

No water should be used for drinking purposes containing even a trace of lead, for, however minute it is, its presence in the water indicates danger. Very often the sample examined will not represent the daily maximum. See Lead Poisoning, page 1155.

**EXPRESSION OF CHEMICAL RESULTS**

Formerly results were expressed in grains per gallon. After the introduction of the metric system results were expressed in parts per 100,000, but now results are commonly expressed in parts per million. The latter method has the advantage that 1 milligram is 0.000,001 liter, and, therefore, 1 milligram in 1,000 c. c. = 1 part per million. A liter or a fraction thereof of the water to be analyzed is used, which greatly simplifies the calculations.

Of course, the assumption is made that a liter of water weighs a kilogram. This is sufficiently accurate for potable waters, but introduces an error where mineral waters are dealt with whose specific gravities are appreciably higher than unity. In such cases the water may be actually weighed, or else the weight may be estimated from the known specific gravity and volume.

The results expressed in parts per 100,000 or in grains per gallon may be transformed to parts per million, or, conversely, by the use of the following table:

	Grains per U. S. Gal- lon	Grains per Imperial Gallon	Parts per 100,000	Parts per 1,000,000
1 grain per U. S. gallon.....	1.000	1.20	1.71	17.1
1 grain per Imperial gallon..	0.835	1.00	1.43	14.3
1 part per 100,000.....	0.585	0.70	1.00	10.0
1 part per 1,000,000.....	0.058	0.07	0.10	1.0

## CHAPTER III

### MICROSCOPICAL EXAMINATION OF WATER

The chief object of the microscopic examination of water is the determination of the presence or absence of those microörganisms which produce objectionable tastes and odors. In certain cases the determination is also of value as an index of pollution or as a guide to the identity of the water. The microscopical organisms comprise the Diatomaceae, Chlorophyceae, Cyanophyceae, Fungi, Protozoa, Rotifera, Crustaceae and other organisms minute in size, but not including the bacteria. Fragments of organic matter, broken-down organisms, zoöglea, etc., should be termed amorphous matter. Clay, silt, oxid of iron, and mineral matter in general are not included under amorphous matter and are not measured by microscopic examination.

The term "microörganisms" as used by the water analyst includes all organisms, whether plant or animal, that are invisible or barely visible to the naked eye, other than bacteria. The bacteria are set apart, inasmuch as their significance and the method of studying them are different from all other microscopic organisms. As Whipple aptly phrases it, "Bacteria make a water unsafe, microörganisms make it unsavory."

The sanitary quality of water cannot be definitely shown from a microscopical examination. Surface waters are usually rich in microscopic life, while ground waters are comparatively free. However, as soon as ground waters stand in pipes or are exposed to the light, microscopic organisms develop.

"Plankton" is the general name given to the microscopic aggregation which is investigated in any given sample of water. The term as used embraces plants and animals that float about in the free state, also larvae, egg masses, etc., of higher animals. It includes diatoms, algae, fungi, protozoa, etc.<sup>1</sup>

**The Sedgwick-Rafter Method.**—This is the standard method for counting the number of microscopic organisms in water. It consists in collecting the microscopic particles suspended in a known quantity of water, and counting them in a cell of known capacity under the microscope. The microscopic particles are collected upon sand by filtration. This is done in a straight-sided cylindrical funnel, shaped and graduated as shown in Fig. 114.

<sup>1</sup> For a full discussion of this subject see "The Microscopy of Drinking Water," by George C. Whipple. John Wiley & Sons, N. Y., 1914.

Moisten a disk of bolting cloth and place it over the small end of the rubber stopper and press it tightly into the lower end of the funnel. Now pour sand on to the bolting cloth, to the depth of about 1 cm. Quartz sand or white alundum may be used, but it should first be washed and ignited; and of such size that it will pass through a sieve having 60 meshes to the square inch, but will not pass a 100 mesh sieve. Sand between 120 and 140 meshes may be used if the water contains very small microorganisms. Now run 250 c. c. of the water to be examined into the funnel without disturbing the sand. Filtration may be hastened either by pressure from above or suction from below; if the water filters too slowly errors will result from many of the microorganisms sticking to the sides of the funnel. When practically all the water has passed off, and the sand begins to dry, hold the funnel in the left hand and slope it so that the sand falls away from the stopper; remove the stopper and quickly slip a test tube over the end of the funnel and allow the sand to flow into it. Without removing the test tube, wash the funnel with 5 c. c. of distilled water. The mixture of sand, microorganisms and water in the test tube is agitated, and the supernatant suspension decanted into a second tube from which 1 c. c. is placed into the counting cell of that capacity. Slip the cover glass into place and count the microorganisms with a specially ruled ocular micrometer and a 2/3-inch objective.

The counting cell consists of a rectangular brass rim cemented to an ordinary glass slide. The inside dimensions of the rim are 50 mm. by 20 mm. by 1 mm., making a capacity of one cubic centimeter. The roof of the cell consists of a cover glass (No. 3) of sufficient size.

The ocular micrometer is so ruled that the largest square is 1 square millimeter; the smallest square is 1 standard unit. The area which the largest square covers on the stage of the microscope should be measured with a stage micrometer and adjusted by changing the length of the draw tube of the microscope so that this large square will measure just 1 square millimeter. A rough and ready ocular micrometer can be made by cutting out a circle of cardboard which will fit into the tube of the microscope, this circle of cardboard having a square cut in its center, the size of the square to be the largest which the diaphragm will allow. It will be found that the

FIG. 114.—GRADUATED CYLINDRICAL FUNNEL AND CONCENTRATING ATTACHMENT USED IN THE SEDGWICK - RAFTER METHOD.

area of the stage which will be included in the field will be approximately 1 square millimeter.

**Recording Results.**—Twenty full squares of 1 mm. each are counted at random, the organisms identified, and the results calculated either by the number of organisms per cubic centimeter of the sample, or, better perhaps, the number of standard units per cubic centimeter of the sample.

The number of organisms per cubic centimeter may be determined from the following equation:

$$\text{Number per cubic centimeter} = \frac{1000W}{N F}$$

W = the number of cubic centimeters of water used in washing the sand.

N = the number of squares counted.

F = the number of cubic centimeters of water filtered.

The standard unit is an attempt to measure the mass rather than the number of microscopic organisms present in the water. By this means a rough estimation of the amount of suspended organic matter is obtained. Whipple, who devised the standard unit method of counting microorganisms, defines the standard unit as a square 20 x 20 microns = 400 square microns. A micron is 0.001 millimeter.

The ocular micrometer used corresponds to the standard unit. A square which covers 1 square millimeter on the stage of the microscope is divided into four equal squares. Each of these is subdivided into 25 equal squares. Each of these contains 25 standard units. The eye can easily divide the side of the smallest squares into fifths, and each of these fifths is the size of a standard unit.

**Significance of the Examination.**—The microscopical examination of water is of great value in supplementing the chemical and bacterial analyses. It may explain the cause of odors and tastes in a water; it may explain certain chemical determinations, as albuminoid ammonia, dissolved oxygen, oxygen consumed, carbon dioxid, etc.; it may indicate sewage contamination; it may suggest the state of self-purification of a polluted water; it may identify the source of the water.

Several of the microscopic organisms, when present in sufficient quantities, give rise to objectionable odors and tastes, either when in a vegetative state or upon decomposition. The natural odors of organisms are due to oils analogous to the essential oils as in peppermint and in certain fishes. In general, the diatoms have an aromatic odor, increasing to that of a geranium leaf, and even to an intensity that is fishy. The cyanophyceae, or blue-green algae, have a grassy or moldy odor. The chlorophyceae have little odor, although some of the motile forms give rise to faintly fishy odors. The ciliated protozoa have in general no

odor. Uroglena, synura, dinobryon, and peridinium may and often do give rise to fishy odors. Of the other microorganisms, the rotifera and crustacea, no forms have been recorded as giving rise to objectionable odors. These forms are present only when there are lower forms upon which to feed. They are scavengers and as such may be considered as desirable elements in water. Their presence, however, calls for an investigation of the nature of their food supply, as it is often furnished by pollution. This does not necessarily hold true in all cases.

Besides these animal and plant forms there may be present also sponges, mosses, yeasts, and molds, the significance of which is varied and dependent upon local conditions.

There are many sources of error in a quantitative determination of the microscopic organisms in water. Some of the organisms stick to the sides of the funnel; some pass through the sand; some are so heavy they settle in the sample, especially if it has been allowed to stand; some are so fragile that they disintegrate readily, and further error may be due to unequal distribution of the organisms in the counting cell. For all these reasons accurate results within 10 per cent. are not possible, and comparative results may only be obtained by careful standardization of methods.

## THE BACTERIOLOGICAL EXAMINATION

Practically all natural waters contain bacteria. This is true of rain water, ground water, and the waters of lakes, rivers, and oceans. The number and variety of the bacteria vary greatly in different places and under different conditions. The bacteria are washed into the water from the air, from the soil, and from almost every conceivable object. The intestinal contents of animals pollute waters with enormous numbers of microorganisms, but it is the infection with certain species from man that makes water most dangerous when consumed by his fellowmen.

A final judgment of the potability of a water should never be given upon the bacteriological examination alone, but should be combined with a sanitary survey. A sanitary survey may discover possibilities of danger, even though the sample examined contains few bacteria and no *B. coli*. On the other hand, a water may contain large numbers and miscellaneous kinds of bacteria and yet a sanitary survey will disclose absence of human pollution.

## THE NUMBER OF BACTERIA IN WATER

The number of bacteria is not as important as the kind, yet much may be learned from a simple enumeration of the bacteria. Roughly speaking, the number of bacteria in water corresponds to the amount

of organic pollution. No known method furnishes a complete census of the bacterial population of a given sample of water. Methods based upon the direct microscopic count of the bacteria do not distinguish between the live and the dead ones; further, only those that may readily be seen by simple methods are thus visible. Many bacteria, especially those pathogenic for man, do not vegetate at  $20^{\circ}$  C., so that the usual counts upon gelatin may vary greatly from those obtained upon agar at  $37^{\circ}$  C. Some varieties require acid, others alkaline media; some are aërobic, others anaërobic; some will not grow unless the medium contains blood or other suitable pabulum, and so on through a wide gamut of conditions.

Although it is not possible to determine the total number, inferences of importance may be drawn from the differences in the numbers of bacteria in a given water obtained by different methods. Thus a water containing great numbers of bacteria, developing on gelatin at  $20^{\circ}$  C., and but few colonies upon agar at  $37^{\circ}$  C., has little sanitary significance, whereas a water containing few bacteria, but most of them varieties that grow upon agar at  $37^{\circ}$  C., with relatively few at  $20^{\circ}$  C., must be looked upon with suspicion. The distinction between polluted waters and waters of good quality is more sharply marked by counts at  $37^{\circ}$  C. than is the case with counts at  $20^{\circ}$  C. Another advantage of growing the plates at a higher temperature is that the results are available in a much shorter time.

The number of bacteria which grow at  $40^{\circ}$  C. may be of special value, since this class includes the typhoid bacillus and other water-borne pathogens, but excludes the common water bacteria of little sanitary importance.

From Germany we have the arbitrary standard based upon the dictum of Koch that a good water should not contain over 100 bacteria per c. c. This is a good working rule, but should not be taken too literally. Thus, water may contain great numbers of the common aquatic bacteria which vegetate at room temperature and which are not harmful to man. Surface waters contain the greatest numbers on account of exposure to contamination to which they are liable; rain waters contain comparatively few, excepting the first shower through a very dusty atmosphere; ground waters from the depths are practically sterile. Unpolluted shallow well waters are also exceptionally free. The number and significance of the bacteria, therefore, vary with the source of the water. For example, a hundred bacteria, including a few colon bacilli, of the fecal type, in a well water would be regarded with great suspicion, whereas a hundred or more bacteria, with an occasional colon bacillus, in a river water draining an uninhabited watershed would be normal.

The number of bacteria in water depends somewhat upon the manner in which it is stored. Thus a water containing a few organisms

placed in a closed bottle and kept at room temperature may, at the end of 24 hours, contain hundreds or thousands per c. c. I once examined a deep well water that was practically sterile as it came out of the earth, but when stored in a cistern gave over a thousand organisms per c. c. These came from the multiplication of the bacteria that entered the water from the air, dust, leaves, and other sources. On the other hand, water stored in impounding reservoirs shows a marked diminution in the number of bacteria.

The numerical determination of bacteria in water is of very great value when studying surface waters, such as lakes and rivers. As a rule, the number of bacteria is proportional to the pollution of a river—not necessarily fecal pollution, but pollution from dead organic matter of one kind or another. The bacterial content of a river water varies sharply from time to time. Contrary to the usual opinion, a river contains more bacteria in the winter time than in the warm weather. During times of freshets or turbidity the number of bacteria will rise very abruptly. In other words, the number of bacteria in a stream is an index of its turbidity. It is an interesting fact that in the Potomac and other rivers the bacterial curve does not correspond to the typhoid fever curve. Typhoid in Washington is highest in summer, but the bacteria are most numerous in winter. While sudden variations in the number of bacteria have a ready explanation in the case of turbid and torrential rivers, in the case of lakes, and especially in a ground water, variation in numbers indicates nearby sources of pollution and is a danger signal. For shallow wells the interpretation of numbers is not so easy, largely because infection may enter at the surface. Wells which are poorly protected at the top will always show an unusually large number and variety of bacteria.

Numerical determination is also of importance in tracing imperfections and leaks in a water supply. Thus Dr. Shuttleworth, of Toronto, was able through this means to suspect a broken water main, and upon examination it was found that a whole section of the conduit had dropped out of place, so that the supply was being taken from the lake near the shore instead of some distance away where the intake was located.

The great value of the numerical estimate of bacteria is well known in determining the efficiency of filters.

**Method for Determining the Number of Bacteria in Water.**—The standard medium for determining the number of bacteria in water is a nutrient agar having a reaction of +1 per cent., using phenolphthalein as an indicator. If the reaction is between +0.5 per cent. and +1.0 per cent., it is not adjusted. A liter of nutrient agar consists of 3 grams of beef extract (Liebig's preferably), 5 grams of peptone, 12 grams of oven dried agar, and 1,000 c. c. of distilled water.

The sample of water must be shaken vigorously at least 25 times

in order to break up the bacterial clumps and to obtain a uniform suspension. If the water contains less than 200 bacteria per c. c., 1 c. c. of it may be placed directly in the petri dish, then add 10 c. c. of the standard medium. Mix well, congeal, invert the plates, and incubate at 37° C. for 48 hours in a dark, well-ventilated incubator where the atmosphere is practically saturated with moisture. When gelatin is used the plates should be incubated at 20° C. for 4 days. If there is reason to believe that the number of bacteria is more than 250 per c. c., dilute by mixing 1 c. c. of the sample with 9 c. c. of sterilized tap or distilled water. Again shake 25 times and plate 1 c. c. of the dilution. Higher dilutions may be made in 99 c. c. and so on. In the case of an unknown water or sewage it is customary to use several dilutions of the same sample. It is desirable to use such portions of the sample as will give between 25 and 250 colonies on duplicate plates. Count the colonies upon a Wolffhügel apparatus or a Jeffer's plate, using a lens of  $2\frac{1}{2}$  diameters,  $3\frac{1}{2}$ " focus. It is not necessary for one who wears glasses to remove same while counting. The whole number of colonies on a plate should be counted, the practice of counting a fractional part being resorted to only in cases of necessity.

When agar is used for plating it may be found advantageous to use Petri dishes with porous earthenware covers in order to avoid the spreading of colonies by the water of condensation.

In order to avoid fictitious accuracy and yet express the numerical results by a method consistent with the precision of the work, the table below should be followed in expressing the numbers of bacteria per c. c.:

From	1 to	50	recorded as found	
"	51	"	100	" to the nearest 5
"	101	"	250	" " " " 10

### KINDS OF BACTERIA IN WATER

Water analysis is in its infancy so far as methods for determining the kinds of bacteria are concerned. It is comparatively easy to isolate colon bacilli and to determine their approximate number in a water. It is also comparatively easy to isolate cholera vibrio. Methods for determining whether a water does or does not contain typhoid, dysentery, and other pathogenic parasites are tedious, difficult, and often impossible in the present state of our knowledge.

A certain amount of information may be gleaned from the presence and number of organisms belonging to certain groups, such as chromogenic, liquefying, and fermenting types. Chromogenic organisms exist everywhere in surface waters. They should be practically absent from ground waters. The same is true of organisms that are able to liquefy gelatin and ferment sugars. The chromogenic, proteolytic and fermenting types are widespread in nature and exist almost everywhere in the air, the soil, and in surface waters. Their presence in a ground water signifies contamination or pollution, often from the surface.

The significance of the various types of bacteria that grow at different temperatures has already been discussed.

### THE COLON BACILLUS

The *Bacillus coli* group is very widely distributed in nature. The normal habitat of certain members of this group may be regarded as the intestines of man and many other animals. The colon bacillus is usually taken as an index of pollution. The sanitary significance of colon bacilli in water varies with their number and, further, with their source. While the colon bacillus indicates pollution, it does not necessarily signify danger, that is, infection.

By common consent a ground water should be condemned if it contains even a few colon bacilli of fecal type, for these organisms have no business in a soil-filtered and properly protected well or spring water.<sup>2</sup> Surface waters are not regarded as particularly suspicious, provided they have not more than one colon bacillus per c. e., especially if the surface water is known to drain an uninhabited or controlled catchment area. Many of the colon bacilli in a surface water come from the droppings of wild and domestic animals and, therefore, are infinitely less indicative than those that come from the intestinal tract of man. Tests for the colon bacilli in water must, therefore, be qualitative and quantitative.

**Types of *B. Coli*.**—There are various types in the colon bacillus group. One type, believed to be of *fecal* origin, is characterized by (1) a low gas ratio—approximately equal volumes of carbon dioxid and hydrogen; (2) a red reaction with methyl red, indicating a high hydrogen ion concentration; and (3) a negative Voges-Proskauer reaction, indicating the absence of a certain type of decomposition of dextrose. The other type, believed to be *non-fecal* in origin and sometimes included in the *B. aërogenes* group, has (1) a high gas ratio—two volumes of carbon dioxid to 1 volume of hydrogen; (2) a yellow reaction with methyl red; and (3) a positive Voges-Proskauer reaction. These distinctions are not absolute, for *B. coli* of non-fecal (*aërogenes*) type

<sup>2</sup> Carbonated bottle waters may contain *B. coli* in relatively large numbers.

may be found in fresh feces—although relatively few occur in man, more in other animals. Appropriate laboratory tests to determine types of the colon group, combined with a sanitary survey of the watershed, will do much to indicate the probability of fecal contamination. See tests given below.

The absence of colon bacilli in water proves its harmlessness so far as bacteriology can prove it. It is fair to assume that typhoid bacilli, dysentery bacilli, and other intestinal parasites would not be likely to be present in a water in the absence of the colon bacillus. It is possible to conceive that in rare instances a water may be polluted with urine alone containing typhoid bacilli, but no colon bacilli.

**Tests for the Colon Bacillus.**—Presumptive tests or partial tests are sometimes used to determine the presence of *B. coli*. These tests are fairly reliable, and afford useful information. They consist, as a rule, in planting small quantities of the water sample in lactose bouillon in fermentation tubes and incubating at 37° C. for 24 to 48 hours. Under these circumstances it may be presumed that in the absence of fermentation colon bacilli are absent, and that fermentation with gas production suggests their presence. Both these conclusions may be misleading. Grossly polluted waters containing many colon bacilli may be slow in fermenting sugars with the production of gas on account of the preponderance of other more active species. On the other hand, many organisms other than the colon bacillus often found in water ferment sugars with gas production. It is therefore necessary to isolate the suspected organism in pure culture and pass it through the well-known tests before it is labeled *B. coli*.

**Presumptive Tests for *B. Coli*.**—A satisfactory method consists in inoculating a 10 c. c. portion of sample into each of five fermentation tubes containing from 30 to 40 c. c. of lactose broth. In order to obtain a sufficiently low dilution, so that no fermentation will result in one tube in the series 1 c. c., 0.1 c. c., 0.01 c. c., or even 0.001 c. c. (if heavy pollution is suspected), portions of the sample may be inoculated into lactose fermentation tubes. When such small quantities of water are tested, less than 30 c. c. portions of media may well be used. The fermentation tubes described above should be incubated 48 hours at 37° C. The presence of 10 per cent. or more of gas constitutes a presumptive test.

If in such a series fermentation with gas production occurs in the tubes containing 1 c. c. or more, but does not take place in the tubes containing the smaller portions, it may then be stated that the water contains at least one colon bacillus per cubic centimeter, *provided* the isolation tests show that the fermentation was caused by this organism.

The number of colon bacilli may also be determined approximately by planting the water directly upon the surface of lactose litmus agar or

Endo's medium. The red colonies should then be studied to determine how many of them are *B. coli*, and the number may thus be approximated per cubic centimeter.

*Confirmation Tests for B. Coli.*—Cultures should be made on Endo's or litmus lactose agar plates from tube showing gas with smallest portion of sample, and incubated 24 to 48 hours. If typical colon-like colonies form, at least two from each sample should be inoculated on agar slants and tubes of lactose fermentation medium for further confirmation. If, after 48 hours, no typical colon colonies develop on the Endo's or litmus lactose agar plates, two colonies appearing nearest like coli are treated as above. From the agar slant, examinations may be made to demonstrate that the organism in question is a short, gram negative, non-spore-forming rod. If sufficient organisms of the *B. coli* group have been found to render the water questionable, further studies should be made to determine their type, that is, whether fecal or non-fecal. This may best be done from colonies on Endo's or litmus lactose agar plated directly from the water, at least 10 or 12 colonies being studied. If no direct platings from the sample are available, a similar study may be made of cultures obtained from fermentation tubes, but these may all be descendants of a single cell in the original sample.

**Differentiating Fecal from Non-Fecal *B. Coli***—*The Gas Ratio Test.*—The earlier workers in this subject defined *B. coli* as an organism producing gas from dextrose, consisting of one volume of carbon dioxid to two volumes of hydrogen. More recent work indicates that the fecal coli usually produce carbon dioxid and hydrogen in about equal volumes, and is thus a low gas ratio organism. Organisms of the colon group are frequently obtained from soil, seeds, fruit, leaves, and many other similar non-fecal sources. Pollution of a water supply by bacteria from such a source would not in itself indicate direct fecal contamination. Such organisms usually differ from the fecal type in that they produce carbon dioxid and hydrogen in a ratio of 2:1 or 3:1 (high ratio type). Feces of different animals as a rule contain a small percentage of this non-fecal type of organism.

*The Methyl Red Test.*—The fecal type of *B. coli* produces a relatively high concentration of hydrogen ions in dextrose broth, and this correlates very well with low gas ratio. The non-fecal type, in addition to having a high gas ratio, is characterized by a relatively low hydrogen ion concentration. This may be determined by the addition of methyl red to cultures of dextrose broth. The former (fecal type) will give a red color, = acid or methyl-red-positive, and the latter (non-fecal type), yellow, = alkaline or methyl-red-negative.

*The Voges-Proskauer reaction* is also useful in differentiating between the various members of the *B. coli* group. To 5 c. c. of a dextrose broth culture, add 5 c. c. of a 10 per cent. solution of potassium hy-

droxid. Allow this to stand 12 to 18 hours. A positive test is indicated by an eosin pink color, and is seldom given by a positive-methyl-red organism. This production of pink color with a fluorescence is probably due to action of acetyl-methyl-carbinol (one of the by-products in decomposition of dextrose by bacteria) on peptone in the presence of alkali. In general, the methyl-red positive, and Voges-Proskauer negative organisms may be assumed to represent *B. coli* of fecal origin; methyl-red negative, Voges-Proskauer positive, *B. aërogenes* type, and most of these not fecal in origin. The presence in any considerable amount of organisms of the *B. coli* group would render the water questionable, and it would not seem advisable to certify to its purity on laboratory evidence alone, even if the organisms did appear to belong to the so-called non-fecal type.

#### SEWAGE STREPTOCOCCI

Fresh sewage from man and other mammalian animals usually contains streptococci resembling the *Streptococcus pyogenes*. At present little stress is placed upon isolation of these types, and the general consensus of opinion is that the occurrence of these organisms in a water is of less significance than *B. coli*; the streptococcus test is therefore of subordinate importance.

#### TYPHOID BACILLUS

The search for a typhoid bacillus in water is frequently like looking for a needle in a haystack; in fact, it has seldom been isolated from a drinking water. It is probable that the typhoid bacillus rarely, if ever, multiplies in natural waters. The dilution is usually enormous, and their number is therefore comparatively few. With modern methods and the use of Endo's medium it is comparatively easy to isolate typhoid bacilli from water richly seeded with these organisms, but it is practically a hopeless task to find them when there are only a few in a glassful. Great care must be exercised before an organism isolated from water is reported as *B. typhosus*. There are many organisms in water closely resembling typhoid, some of them even giving pronounced agglutination with specific serum. Thus *B. proteus*, *B. fluorescens*, and even *B. coli* sometimes agglutinate with typhoid serum and in higher dilutions than typhoid strains themselves. An interesting instance of this was found in our studies of the Potomac River water. Frost isolated an organism, the "*Pseudomonas protea*," from the filtered Potomac River water which, during the months of August, September, and October, 1909, was more common than *B. coli*. This organism could not be found in the raw water, nor could it be found in a large number of stools examined, which points to a saprophytic existence. This organism may readily be distinguished from *B. typhosus*, in that it has dif-

ferent cultural characters, and further that animals injected with cultures of *Pseudomonas protea* develop agglutinations for this organism, but not for *B. typhosus*.

### CHOLERA

The cholera vibrio may be detected in water by making a Dunham's solution of the water itself; that is, to a large quantity of the water sample add sufficient peptone to make a 1 per cent. solution, and render slightly alkaline with sodium carbonate. The water should be placed in Erlenmeyer, Fernbach, or similar flasks, presenting a large surface favoring aërobic development. The flasks are then placed in the thermostat at 37° C. and in 16, 18, 24 hours, or longer, a loopful of the surface growth is planted upon agar, Endo's medium, or gelatin. Cholera colonies upon gelatin have a ground-glass appearance when examined under a low power of the microscope, with irregular margins, and the gelatin is slowly liquefied. Upon agar the colonies are not particularly distinctive; upon the surface of Endo's medium cholera grows as faintly pinkish, moist, translucent colonies, not unlike typhoid colonies, excepting that they have slightly more color.<sup>3</sup> Dependence cannot be placed upon the appearance of the colonies nor upon the morphological characteristics of the organism. Suspicious colonies should be isolated and tested with an agglutinating serum of known specificity having a high agglutinating value. All organisms that are agglutinated with this serum in a dilution of 1-1,000 or over may be regarded as cholera. This, however, should not be accepted as final, for, as is the case with typhoid, there are numerous cholera-like organisms in water that agglutinate with a cholera serum, but which upon further study have characteristics which plainly show that they are not the organism which causes cholera. Final dependence should be placed upon Pfeiffer's phenomenon and upon cross-agglutinating tests or absorption tests to eliminate the phenomenon of group agglutination.

<sup>3</sup> See also pp. 111, 140, and 144.

## CHAPTER IV

### INTERPRETATION OF SANITARY WATER ANALYSIS

The interpretation of a sanitary water analysis is much more difficult than the analysis itself, where everything may be carried out by rule of thumb in accordance with standard procedures. Single or occasional determinations of either the chemical or bacterial properties of water are of little value. A single water analysis is often misleading, especially in surface waters, which may vary greatly from time to time. A river water may require repeated examinations extending over long periods of time correlated with conditions of rainfall, stream flow, wind, temperature, sewage pollution, and other factors in order to be helpful.

There has been much conflict and useless discussion between chemists and bacteriologists concerning the relative advantages of their methods. The chemists were first in the field, but the limitations of chemical methods were strongly emphasized when it was shown that chemistry can only indicate pollution but cannot discover infection. Much was hoped from bacteriology, but it is rather exceptional that bacteriologists are able to isolate pathogenic microorganisms from a sample of water. For the most part, the routine bacteriological examination of water does nothing more than the chemical examination, that is, it shows pollution but does not prove infection. Both chemical and bacterial analyses of water have, therefore, distinct limitations; they do not antagonize, but supplement each other. From the chemical side we learn much of the past history of a water; the bacteriology tells us more of its present state. Chemical methods reign supreme when we desire to discover the presence of lead or other inorganic poisons; also in determining the hardness, mineral and organic constituents, etc. From the number and character of the bacteria in water we obtain a fair index of the presence and degree of pollution. Occasionally bacteriologists may determine whether a water contains certain specific agents, such as cholera vibrio. It must, however, be admitted that the ordinary routine chemical and bacterial examination of water affords but meager information, especially when only one analysis has been made. Fortunately, the inferences drawn from a sanitary water analysis are on the safe side, for many good waters are condemned, so that it would be very difficult for an unsafe water to pass the muster of a

complete sanitary analysis. At most, the information furnished is only of present conditions and is not a guarantee of future safety. A surface water or a ground water may today be exceptionally free from chemical impurities and practically sterile bacteriologically, whereas tomorrow it may contain typhoid, dysentery, cholera, or other water-borne infections; these may come from sources that would at once be perfectly evident from a sanitary survey of the watershed.

A sanitary survey of the catchment area is frequently of much greater practical importance than all the information furnished by the laboratory. It needs neither chemists nor bacteriologists to tell us that the water from a creek with an overhanging privy a short distance above will some day carry infection; or that the water from a shallow well in limestone or coarse gravel very near a leaking cesspool must be a source of danger. A sanitary survey is able to discover the sources of contamination, the kinds of pollution, and the degree, often with greater precision than combined chemical or bacteriological tests. No sanitary analysis of a water can therefore be considered complete unless it includes an examination of the watershed and a study of the geology and topography of the catchment area.

From a sanitary standpoint, the principal substances to look for in a chemical analysis are the organic matter, nitrates, nitrites, and chlorin. Of these the nitrites are the greatest danger signal, indicating oxidation of organic matter through bacterial activity. High chlorin and nitrates without nitrites indicate passed or remote pollution; this is a frequent combination in ground waters. The ammonias (free and albuminoid) are a measure of the amount of nitrogenous organic matter in the water. A surface water may safely contain an amount of albuminoid ammonia that would be suspicious in a ground water. The significance of the chlorin varies with the location and source of the water. Ground waters should contain fewer bacteria than surface waters. Artesian wells should be practically sterile, and a good surface water should not contain over 100 bacteria per cubic centimeter. Waters that vary in composition from time to time without evident cause must be regarded as unsafe. This applies particularly to ground waters. Surface waters vary greatly as the result of freshets, etc., but a ground water, pond, or lake should show no sudden variations.

These general statements may be quite misleading when interpreting the analysis of a specific case. Therefore several selected analyses and interpretations have been given below.

**Allowable Limits.**—The following are sometimes considered as the allowable limits of the impurities commonly regarded as permissible in drinking water.

Chlorin depends upon the normal chlorin content of unpolluted surface waters in the neighborhood.

Bacteria not over 100 per cubic centimeter.

Colon bacillus should be absent from the ground water and not more than 1 per 10 c. c. in a stream or in a river water.

Free ammonia.....	0.015-0.03
Albuminoid ammonia.....	0.07 -0.35
Nitrogen as nitrites.....	None, or at most a trace (0.0001)
Nitrogen as nitrates.....	0.3 to 1.6
[Parts per million]	

The standard adopted by the government<sup>1</sup> for drinking water supplied by common carriers in interstate commerce and also for bottled waters demands that the total number of bacteria shall not exceed 100

FIG. 115.—DIAGRAM ILLUSTRATING THE CHARACTER OF THE GROUND WATER IN RELATION TO SOIL POLLUTION, TO ASSIST IN THE INTERPRETATION OF A SANITARY ANALYSIS. See also Nitrogen Cycle, page 998.

per cubic centimeter when grown on standard agar plates and counted after twenty-four hours' incubation at 37° C. Further, that not more than one out of five 10 c. c. portions of any sample examined shall show the presence of organisms of the bacillus coli group. Later (February 12, 1917), the requirement was added that the source of water supplied interstate carriers be free of contamination.

According to the International Boundaries Commission, a raw water containing over 500 B. coli per 100 c. c. is too polluted for use even after purification.

Bacteriological standards for drinking water supplied common carriers in interstate commerce are given in the U. S. Public Health Reports, November 6, 1914.

These figures must not be taken literally, and are not given as

<sup>1</sup>Public Health Reports. Nov. 16, 1914. No. 29, Vol. XLV, p. 2959.

standards of purity, but the maximum limits of the impurities allowable under ordinary conditions. It will be seen from the illustrative analyses given below that at times these limits may be exceeded without sanitary significance, whereas at other times a water well within the prescribed limits may contain infection.

For a better understanding a number of sanitary analyses of water are given with an interpretation. The student is advised first to study the analyses, draw his own conclusions, and then compare them with the interpretation given.

#### ANALYSIS No. 1—*Gross Pollution*

Free ammonia.....	0.214	part	per	million
Albuminoid ammonia.....	0.810	"	"	"
Nitrogen as nitrites.....	0.005	"	"	"
Nitrogen as nitrates.....	21.0	parts	"	"
Chlorin .....	47.0	"	"	"
Total residue.....	412.0	"	"	"
Volatile residue.....	279.0	"	"	"
<hr/>				
Fixed residue.....	133.0	"	"	"
Bacteria per c. c. upon gelatin at 20° C.....	65,000			
Bacteria per c. c. upon agar at 37° C.....	120,000			

Many liquefying colonies. Many chromogens per c. c.  
 Fermentation in lactose bouillon in 0.001 c. c. *B. coli*  
 present in 0.01 c. c.

This represents a grossly polluted water and should unhesitatingly be condemned, no matter what its source.

The following analysis of the Hamburg public supply from the Elbe River during the cholera epidemic of 1892 is given in *Chemical News*, LXVI, 144:

#### ANALYSIS No. 2—*Elbe River During Cholera Epidemic*

Appearance .....	Turbid and very yellow
Taste .....	Slightly unpleasant
Odor .....	Extremely little
Deposit .....	Small and dirty-looking
Chlorin .....	472.0 parts per million
Free ammonia.....	1.065 " " "
Albuminoid ammonia.....	0.293 " " "
Nitrates .....	26.43 " " "
Required oxygen (15 minutes)....	0.928 " " "
Required oxygen (4 hours).....	3.428 " " "
Total solids.....	1,160.7 " " "

This is given simply as an instance of a grossly polluted river (Elbe) water, known to be infected.

ANALYSIS No. 3—*Boston Tap, Typical* (not averaged results)

Free ammonia.....	0.010	part	per	million
Albuminoid ammonia.....	0.114	"	"	"
Nitrogen as nitrites.....	0.000	"	"	"
Nitrogen as nitrates.....	0.02	"	"	"
Chlorin .....	2.7	parts	"	"
Total residue.....	27.0	"	"	"
Volatile residue.....	10.0	"	"	"
Fixed residue.....	17.0	"	"	"
Hardness, 13°.				
Bacteria per c. c. upon gelatin at 20° C.....				77
<i>B. coli</i> .....				None

This is a surface water, collected in impounding reservoirs and stored about 30 days before it reaches the consumer. The watershed is fairly well protected. The chemical analysis shows little organic pollution; the ammonias are moderate in amount, nitrites absent; nitrates low; chlorin normal; bacteria indicating nothing suspicious. The water is of good sanitary quality, judged by chemical and bacterial analysis.

ANALYSIS No. 4—*A Suspicious Water*

Free ammonia.....	0.018	part	per	million
Albuminoid ammonia.....	0.020	"	"	"
Nitrogen as nitrites.....	0.007	"	"	"
Nitrogen as nitrates.....	1.5	parts	"	"
Chlorin .....	19.3	"	"	"
Total residue.....	106.0	"	"	"
Volatile residue.....	37.0	"	"	"
Fixed residue.....	69.0	"	"	"
Hardness, 33.8°.				

(The residue did not char and gave no odor upon ignition.)

Bacteria per c. c. upon gelatin at 20° C.....	60
Bacteria per c. c. upon agar at 37° C.....	45

No liquefying colonies. One chromogen per c. c. No fermentation in lactose bouillon in 10 c. c. No *B. coli*.

This water came from a driven well at Wenham, Mass. Upon inspection it was found that the well was 400 feet from a stable, 200 feet from a cesspool, and 250 feet from the house.

The first thing that strikes our attention in this analysis is the high chlorin. This, however, lacks sanitary significance, as it is normal for the ground waters of this neighborhood. The hardness of the water is due to the very fertile character of the surrounding soil through which the water percolates. The carbonic acid taken up by the water from the decomposing organic matter dissolves the lime in the soil. The organic matter as represented by the ammonias is quite low. The nitrates are high and indicate that the water has dissolved this end

product of the oxidation of organic matter in its passage through the soil and perhaps in seepage from the cesspool. The noticeable quantity of nitrites indicates that all the organic matter has not been consumed and that the mineralization is not complete. The small number of bacteria present shows that the filtering action of this soil through which the water passes is effective in keeping out sewage contamination either from the surface or from the cesspool. This conclusion is strengthened by the absence of fermenting organisms and especially the absence of *B. coli*. The absence of liquefying bacteria and the presence of an occasional chromogenic organism indicate that there is little or no contamination from the surface and, in fact, upon inspection the platform covering the well was found to be tight and well constructed.

This particular sample of well water shows nothing injurious to health, and if subsequent analyses are equally satisfactory the water may be used without fear for drinking purposes. It is plain, however, that this well needs watching, for it is evident that the soil is already surcharged with organic matter, some of which appears in the water, and a further loading of the soil or a break in the cesspool might readily infect the well.

ANALYSIS No. 5—*Surface Pollution of a Well*

Free ammonia.....	0.022	part	per	million
Albuminoid ammonia.....	0.035	"	"	"
Nitrogen as nitrites.....	0.007	"	"	"
Nitrogen as nitrates.....	1.0	"	"	"
Chlorin .....	19.0	parts	"	"
Total residue.....	356.0	"	"	"
Volatile residue.....	151.0	"	"	"
Fixed residue.....	205.0	"	"	"

(Residue charred upon ignition with disagreeable odor.)

Bacteria per c. c. upon gelatin at 20° C.....	9
Bacteria per c. c. upon agar at 37° C.....	275

Many liquefying colonies. Several chromogens per c. c.  
Fermentation in lactose bouillon in 0.1 c. c. *B. coli* present  
in 1 c. c.

This is a shallow well in Washington, D. C., 28 feet deep, the water standing 4 feet in the well. There is a sewer 60 feet from the well and a privy within a block. The pump is old and of wood and the cover to the well is rotten at the base.

Although this water contains a small amount of organic matter, as indicated by the ammonias, every other factor indicates pollution both present and past. The nitrates and nitrites are high; the chlorin is excessive. It is important to notice that this water has only 9 bacteria per cubic centimeter when judged by the colonies that grow upon gelatin at 20° C. Nevertheless, it contains colon bacilli in 1 c. c., other

## 1102 INTERPRETATION OF SANITARY WATER ANALYSIS

fermenting organisms, as well as liquefying and chromogenic colonies. It is probable that most of the contamination in this case came from the surface, as the well had a very poor and leaky platform. This water should not be used for domestic purposes, and if it did not materially improve after the correction of the platform it should be condemned.

ANALYSIS No. 6—*Well Water, Surface Pollution*

Free ammonia.....	0.007	part	per	million
Albuminoid ammonia.....	0.018	"	"	"
Nitrogen as nitrites.....	0.0005	"	"	"
Nitrogen as nitrates.....	2.5	parts	"	"
Chlorin .....	14.0	"	"	"
Total residue.....	62.0	"	"	"
Volatile residue.....	32.0	"	"	"
Fixed residue.....	30.0	"	"	"

(Residue charred upon ignition and gave disagreeable odor.)

Bacteria per c. c. upon gelatin at 20° C.....	820
Bacteria per c. c. upon agar at 37° C.....	640

Many liquefying colonies. Many chromogens per c. c. Fermentation in lactose bouillon in 1 c. c. *B. coli* in 10 c. c.

This water came from a shallow well in Washington, D. C., 18 feet deep, the water standing 3 feet from the bottom. The rather high nitrates and chlorin in this case represent past pollution. The small amount of organic matter with a trace of nitrites plus the number and character of the bacteria indicate surface pollution. This view is strengthened by the fact that repeated examinations of the water from this well showed marked variations in the number of bacteria. Upon inspection the pump and covering to the well were found in very bad condition, leaky, and with surface drainage toward the well.

ANALYSIS No. 7—*Illustrating Remote Pollution*

Free ammonia.....	0.006	part	per	million
Albuminoid ammonia.....	0.011	"	"	"
Nitrogen as nitrites.....	trace	"	"	"
Nitrogen as nitrates.....	20.0	parts	"	"
Chlorin .....	89.0	"	"	"
Total residue.....	430.0	"	"	"
Volatile residue.....	113.0	"	"	"
Fixed residue.....	317.0	"	"	"

(No charring upon ignition; odor of burning rubber.)

Bacteria per c. c. upon gelatin at 20° C.....	92
Bacteria per c. c. upon agar at 37° C.....	16

No liquefying colonies. No chromogens per c. c. No fermentation in lactose bouillon in 10 c. c. *B. coli* absent.

This is a ground water from a shallow well in Washington, D. C. The well is 29 feet deep and the water stands 4 feet from the bottom. Top is well protected, waste water drains to sewer nearby. There are two privy vaults within two blocks of the well.

The analysis shows high chlorin and nitrates; otherwise nothing suspicious. This means remote pollution. The organic matter has been completely mineralized and the bacteria held back by the soil.

#### ANALYSIS No. 8—*High Chlorin*

Free ammonia.....	0.016	part	per	million
Albuminoid ammonia.....	0.015	"	"	"
Nitrogen as nitrites.....	0.000	"	"	"
Nitrogen as nitrates.....	0.14	"	"	"
Chlorin .....	11.20	parts	"	"

Bacteria per c. c. upon gelatin at 20° C.....	48
Bacteria per c. c. upon agar at 37° C.....	12

No liquefying colonies. No chromogens per c. c. No fermentation in lactose bouillon in 10 c. c. *B. coli* absent.

This water is from a driven well at Beverley, Mass. The analysis shows nothing suspicious, excepting the high chlorin, which is normal for this neighborhood and therefore lacks sanitary significance.

#### ANALYSIS No. 9—*High Free Ammonia; Deep Well*

Free ammonia.....	0.170	part	per	million
Albuminoid ammonia.....	0.000	"	"	"
Nitrogen as nitrites.....	trace	"	"	"
Nitrogen as nitrates.....	0.0	"	"	"
Chlorin .....	3.1	parts	"	"
Total residue.....	115.0	"	"	"
Volatile residue.....	45.0	"	"	"
Fixed residue.....	70.0	"	"	"

No bacteria per c. c. upon gelatin at 20° C.

No bacteria per c. c. upon agar at 37° C.

No fermentation in lactose bouillon.

This water is from a driven well in Washington, D. C., 96 feet deep; water stands 81 feet from the bottom. Good platform and drain, and pump is in first-class condition.

It is exceptionally pure, both chemically and bacteriologically, excepting the large amount of free ammonia. This supposedly comes from the reduction of nitrates.

It is not uncommon to find water from deep wells to be high in free ammonia, and it is assumed that this comes from a chemical reduction under high pressure, and perhaps temperature of the nitrogenous matter in coal and alluvial deposits.

ANALYSIS No. 10—*Rain Water Stored and Polluted*

Free ammonia.....	1.050	parts	per	million
Albuminoid ammonia.....	0.175	"	"	"
Chlorin .....	2.0	"	"	"
Nitrogen as nitrites.....	strong trace	"	"	"
Nitrogen as nitrates.....	0.0	"	"	"
Required oxygen.....	2.25	"	"	"
Total residue.....	20.0	"	"	"

Bacteria per c. c. upon gelatin at 20° C..... 625

No fermenting organisms. No *B. coli*.

This is rain water from a dirty cistern. In appearance the water was clear and good. The analysis shows that the water is dirty and contaminated with organic matter. The bacteriological results indicate absence of fecal pollution. The water is undesirable, but not dangerous, as far as infection is concerned.

ANALYSIS No. 11—*Artesian Well Water, Showing the Effects of Storage*  
(The figures are in parts per million)

	Water Directly from the Well	Same Water from the Storage Cistern
Free ammonia.....	.052	.062
Albuminoid ammonia.....	.003	.016
Nitrogen as nitrites.....	.000	.0007
Nitrogen as nitrates.....	.01	.01

Dissolved oxygen.....	10.65	10.69
Oxygen required.....	.10	.15
Total residue.....	111.0	97.
Volatile residue.....	40.0	30.
Fixed residue (mineral matter).....	71.0	67.
Bacteria per c. c. upon gelatin at 20° C.....	6.0	6500.
Fermentation in lactose bouillon.....	in none	in 0.1 c. c.
<i>B. coli</i> .....	absent	absent

This water is from eight artesian wells at the Government Hospital for the Insane at Anacostia, D. C., 375 feet deep. The water is forced out by compressed air and flows by gravity to the storage cistern, which is of brick and cement, and has a capacity of 80,000 gallons.

It will be observed that this water is low in total solids and is almost free of organic matter as represented by the ammonias, nitrites, nitrates, and oxygen required. The water is clear as it flows from the ground, but soon turns slightly yellowish on account of a small amount of iron in the ferrous state that is oxidized to the ferric salt, which is insoluble and is precipitated upon contact with the air. The amount of chlorin is somewhat large, but has no sanitary significance in this case. The principal point in this analysis is the bacteriology, which

shows the water to be practically sterile as it flows from the ground, but which contains over 6,000 bacteria per cubic centimeter in the storage cistern. These come from the air and other contaminating objects, and illustrate the great growth of the common water bacteria in water stored under these circumstances. The slight increase of the ammonias and nitrites in the cistern water, as compared with the water direct from the well, indicates organic pollution and bacterial activity. The diminution in the residue results largely from separation of the iron. This water is pure and wholesome, despite the fact it contains many more bacteria than that usually allowed. It has been used for some years by about 3,000 persons, who are singularly free from typhoid fever and other water-borne diseases.

ANALYSIS No. 12—*Chemical and Bacteriological Changes in Potomac River Water as the Result of Storage and Filtration*

(The figures are the averages of fourteen representative analyses)

	<i>Dalecarlia</i> Inlet Raw Water Entering Storage Reservoir	<i>Dalecarlia</i> Outlet Raw Water After About 3 Days' Storage	<i>Georgetown</i> Reservoir Second Storage Reservoir (Water Remains Here About a Day)	<i>Washington</i> Reservoir 3rd Storage Basin Water Applied to Filter	Filtered Water from Filtered Water Reservoir

*Analysis No. 12* is a good illustration of the bacteriological and chemical character of a river water, and illustrates the changes that occur during short storage (3 to 5 days) and after filtration through a slow sand filter.

It will be seen from this table that there is a gradual diminution in the amount of free ammonia and a more marked diminution in the amount of albuminoid ammonia. The amount of organic matter as represented by the ammonias is diminished just one-third. The nitrites show an increase during storage of the water, indicating active oxidation, but a marked decrease after it is filtered, showing the rapid completion of the oxidation of the organic matter in the filter. The nitrates

show a tendency to increase in amount, which would be expected as the nitrites diminish. It is evident that storage and filtration have little effect upon the chlorin content of the water. The total residue diminishes as the result of storage, sedimentation, and filtration. It will be noted, however, that this diminution is more marked with the fixed residue than with the volatile residue.

The number of bacteria decreases as the result of storage, but the most marked decrease occurs as the result of filtration. It should be

FIG. 116.—DIAGRAM SHOWING LOCATION OF SAMPLES.  
Analysis No. 13, page 1107.

remembered that all the bacteria in the filtered water do not represent those which have passed the filter. The effect of the few days' storage upon this water does not very materially affect the number of *B. coli*, but there is a marked diminution in their number as the result of filtration.

The analyses of surface waters, shown in the table on page 1107, with diagram showing the locations from which samples were obtained, will repay careful study. This table and diagram were furnished through the kindness of Professor Whipple.

The diagram (Fig. 116) shows the location of the samples employed in Analysis No. 13.

## CHAPTER V

### THE PURIFICATION OF WATER

The ways in which water may be purified for practical purposes are not many. It is worth noting that most of the advances in water purification come from the development of old empiric processes. It is only at long intervals that a new method or principle of treatment is discovered that is important enough to find a permanent place in the art of water purification.

The principal methods at present serviceable for the purification of water upon a large scale are: (1) storage, (2) filtration, (3) chemicals, such as ozone, hypochlorite of lime, sulphate of aluminium or iron, (4) ultraviolet rays.

No method of purifying water can be considered to approach a satisfactory hygienic standard that does not first of all practically eliminate water-borne diseases. The process must also reduce the turbidity and color to inappreciable amounts and remove something like 99 per cent. of the bacteria, when these organisms result from sewage pollution and are fairly numerous: there is perhaps no final reason for the bacterial standard. It has been adopted by consent because it represents a purification that is reasonably satisfactory and that can be accomplished at small cost. With the further awakening of the sanitary conscience of the community the standards will inevitably tend higher, and it is probable that in time our standards will approach an ideal that is now not regarded as necessary. At present there is no evidence that the few microörganisms left in the water after a satisfactory method of purification, such as slow sand filtration, are injurious. Certainly, if injurious influence is exercised, it is too small to be determined or measured by any methods now at our disposal.

### NATURE'S METHODS OF PURIFYING WATER

In nature, water is purified by various methods, the chief of which are: (a) evaporation and condensation, which makes rain water the purest of natural waters; (b) the self-purification of running streams, which is a variable and uncertain quantity; (c) storage in lakes and ponds which clarifies water and in time eliminates danger; and (d) the physical, chemical, and biologic action of the soil upon water that

filters through the soil into the earth, which is one of nature's greatest purifying agencies.

**Evaporation and Condensation.**—The purifying action of the distilling and condensing process through which all meteoric water passes is one of nature's beneficent processes. Enormous quantities of sea water, marsh water, and polluted water of all kinds are thus returned to us suitable for domestic use. Somerville estimates that "186,240 cubic miles of water are annually raised from the surface of the globe in the form of vapor chiefly in the intertropical seas." Water is thus constantly being purified in nature. The ocean has been compared to a boiler, the sun to a furnace, and the atmosphere to a vast still. The cooler air of the higher atmosphere and colder zones acts as a condenser, causing the precipitation of the distilled water as rain. About three-fourths of the earth's surface (145,000,000 square miles) is covered with water, much of which is in the tropical belt.

**Self-purification of Streams.**—Streams become purer during the course of their flow. Of this there can be no doubt. This half-truth based upon chemical data has in the past suffered sanitarians to permit the use of water that now we know was responsible for much sickness and many deaths. Streams become purer, but not pure. Some impurities always remain, that is, the process is not complete and final. All surface supplies are now regarded with suspicion and are stored, filtered, or otherwise purified before they are used by educated communities.

It was formerly said that a stream purifies itself in seven miles. Such a generalization is absurd. We now know that it is not the distance so much as the time and opportunity for the various factors involved to become effective. Thus, Buffalo's sewage flows to Niagara's intake, a distance of about 16 miles, in a few hours. There is little chance for self-purification to take place, and despite the great dilution the danger is very great. Niagara's average typhoid rate for 10 years, from 1899 to 1908, was 132.9 per 100,000, the highest in the country. A brisk flow brings the microorganisms of disease alive and virulent to the intake of the water works below; sluggish flow or stagnation corresponds to storage and results in the destruction of most of the bacteria which cause water-borne infections.

A good instance of self-purification of streams was found in the studies of the Potomac River and its relation to typhoid fever in the District of Columbia. The Potomac River drains an area of about 11,400 square miles which, in 1900, contained a population estimated to be about half a million, or about 44 per square mile. The velocity of the flow of the Potomac is extremely variable. It takes from 4 to 7 days for the water to travel from Cumberland to Great Falls (where the Washington intake is located), a distance of about 176 miles. The

waters of the Potomac are directly polluted by sewage at numerous points. The direct pollution is contributed by about 45,000 individuals, or 9.1 per cent. of the total population on the watershed. Of this pollution about 80 per cent. enters the river at points 176 or more miles from the intake at Great Falls, about 15 per cent. enters it at points between 50 and 170 miles above Great Falls, and 5 per cent. is contributed by about 2,200 of the population and enters the river at points between 19 and 50 miles above the intake. There is practically no direct pollution of the Potomac within 19 miles of the intake. Here we have an instance of a stream draining an extensive and populous area and receiving industrial and human wastes from many thousand persons. Nevertheless, self-purification has occurred to such an extent that little, if any, of the typhoid fever occurring in Washington could be attributed to the use of this water.

The Mississippi River is perhaps one of the best examples of the self-purification of a stream, for, after draining almost the entire continental United States in a flow of over 3,000 miles, it is exceptionally free of intestinal bacteria at New Orleans, judged by the comparative absence of colon bacilli.

The principal factors concerned in the self-purification of water are varied and interesting. They are: (1) *Chemical*, the oxidation of nitrogenous organic matter, resulting in its reduction or mineralization; (2) *biologic*, the death of microorganisms through antibiosis, time, and various means; and (3) *physical*, such as dilution, sedimentation, sunlight, etc.

*Oxidation*.—Organic matter is gradually oxidized, thus diminishing the amount of food for bacteria. The activity of the oxidation depends largely upon the amount of dissolved oxygen in the water. It is therefore favored by falls, rapids, and a turbulent flow. It is mainly the aërobic bacteria which have an active proteolytic action, and are thus able to digest and destroy organic matter. During the course of flow the complex nitrogenous substances are thus mineralized. Chemical analyses show a rapid decrease in the amount of organic matter and an increase of nitrates, and diminution of nitrites. It was these facts that led chemists to conclude that flowing rivers soon purified themselves.

*Biological Factors*.—Minute animals, such as infusoria, amebae, water-worms, water-fleas, etc., which exist in countless numbers in certain waters, feed upon the organic matter and bacteria, and are a considerable factor in the self-purification of water.

*Time and antibiosis* play an important rôle in self-purification of streams, as they do elsewhere. Pathogenic bacteria die more quickly in a polluted water than in a pure water. It is probable that symbiosis and antibiosis here plays a part. The saprophytic bacteria somehow help

to kill off the dangerous varieties. Pettenkofer believed that the greater part of self-purification is due to the growth of algae and other low forms of vegetation which clear the water of its impurities in the same way that the higher plants utilize the decomposing manure on cultivated fields. This view is endorsed by Bokorny, Emerisch, and Br  ner and others who have studied the question. It is proved that these plants take up all manner of organic substances. This includes volatile fatty acids, amino-acids, glucose, and urea. The purifying effects of water vegetation are therefore placed near the head of the list of self-purifying agencies.

*Dilution and Sedimentation.*—Dilution is one of nature's real sanitary blessings. The abundance of water quickly dilutes the impurities under ordinary conditions so as to render them harmless. A small amount of infection in a great volume of river or lake water soon becomes so diluted as literally to become lost. It is true that one germ may cause disease just as a spark may start a forest fire, but the conditions must be exceptionally favorable. It is fortunate for us that a single typhoid, cholera, or dysentery bacillus, especially when attenuated, may not, as a rule, induce disease. It is further clear that the chances of receiving a single bacillus in the few glasses of water one drinks are mathematically very small when the dilution is very great. Owing to these facts and to the further fact that pathogenic spore-free bacteria soon become attenuated and die in water, dilution becomes one of our chief sanitary safeguards.

Sedimentation is favored by a slow-moving stream containing insoluble inorganic particles such as clay. In muddy streams such as the Mississippi and Potomac Rivers the water is purified in very much the same way that the snow clears the air. The particles, constantly settling, wash the water by enmeshing the bacteria, which are thus carried to the bottom, where they are imprisoned and die. It is almost a filtration process. The water is swept or scoured many times by the innumerable fine particles in a turbid stream. This is the same principle used to clarify water with chemical coagulants such as sulphate of alumina.

*Sunlight.*—The germicidal influence of sunlight exerts its power upon all surface waters. The depth of penetration is slight, but varies somewhat with the turbidity of the water, the strength and direction of the sun's rays, and other factors.

*Storage in Lakes and Ponds.*—Nature makes use of the purifying power of time in storing water in lakes and ponds and other surface collections. Very few parasites pathogenic for man multiply in water under natural conditions. In time they all die out. Hence a stored water is reasonably safe. In addition, the organic matter undergoes decay and returns to its simple mineral constituents. Hence a stored water will in time free itself not only of harmful parasites, but also of most

of its organic pollution. The stagnation of stored water has been described on page 1030.

The purifying power of the soil has been fully discussed in connection with the nitrogen cycle (page 998).

### **DISTILLED WATER**

The distillation of water is the only method known for rendering it pure in a chemical sense. From a hygienic standpoint it is ideal; from a practical and economic standpoint it has several objections. It is used especially on naval and other vessels and in some industries.

In the distillation of water the first portion of vapor contains a disproportionate amount of volatile impurities, if such are present. If the distillation is continued to dryness or nearly so the concentrated solution of mineral and organic matters suffers reactions by which more volatile matter is formed and the distillate is again contaminated. For these reasons standard distilled water usually includes only what is technically termed the "middle run of the still," some of the first portion being rejected and the distillation stopped before all the water passes over.

Distilled water, even when obtained with precautions, is not always acceptable for drinking purposes. The taste is flat and suggestive of scorched organic matter. This is often ascribed to the want of aëration, but in many cases the sample is not improved by thorough aëration. Even when so improved, the additional operation adds expense, and unless purified air is used it adds organic matters living and dead. Leffmann believes that the disagreeable taste of distilled water is often due to volatile matter.

The economic production of a high-class distilled water is to be desired both from a sanitary and technical point of view, such as for use by brewers and bottlers of soft drinks, laundries, paper mills, and many other processes requiring clean and pure water.

Statements are occasionally made that distilled water is too pure and hence not well adapted for drinking purposes, but these statements are not based upon physiological principles or clinical experience.

### **BOILED WATER**

Boiling renders water safe so far as water-borne infections are concerned. It also destroys the true toxins and probably renders most poisonous substances of organic origin that may be in the water harmless. Water containing lead and other stable chemical substances injurious to health would not, of course, be rendered safe by boiling.

For the traveler, the camper, and others who must use water of various sources, the character of which cannot be readily ascertained, the only safe procedure is to have his own tea kettle and little alcohol lamp. Enough water may be boiled in a few minutes in the morning or evening to last twenty-four hours or more for personal use. Chlorinated lime may also be used for this purpose. See page 1139.

Boiling drives off the dissolved gases, which gives to boiled water a flat taste. This may be corrected by shaking the water in a bottle or stirring with an egg-beater, or simply exposing it to the air over night, care being taken not to recontaminate it. The disagreeable taste of boiled water is partly due to changes in the organic matter which take place at 100° C. As a matter of fact, it is not necessary actually to boil water to render it safe so far as typhoid, cholera, dysentery, and other non-spore-bearing infections are concerned. A temperature of 60° C. for twenty minutes or 70° C. or 80° C. for a few moments is sufficient. However, in the kitchen, where thermometers and scientific care are not expected, it is better to require the water actually to boil to insure safety, especially in waters known to be infected or during epidemics. Boiled water may be kept in covered pails or conveniently placed in well stoppered bottles, in which case it may be iced without the risk of contamination.

## FILTERS

**Slow Sand Filters.**—Slow sand filters, also called English filter-beds, consist of large, shallow, tight reservoirs suitably underdrained and containing some five or six feet of stratified filtering material of progressive degrees of fineness, beginning at the bottom with broken stone or gravel and ending with an upper layer of fine sand. The water is passed through such a filter very slowly, from above downward. The cleansing of such a filter is done by removing the surface layer of dirty sand.

Slowly passing water in this way through sand purifies it biologically, physically, and chemically; nearly all of the objectionable bacteria as well as other microorganisms are removed and many of the particles in suspension are strained out and much of the organic matter is oxidized.

This process is called "slow" sand filtration to distinguish it from the rapid process known as mechanical filtration. The slow sand filters are spoken of as the English method, or as English filter-beds, because it was in England that they originated;<sup>1</sup> whereas the mechanical filters

<sup>1</sup>The first recorded attempt to filter water through sand was in 1829 when the one-acre slow sand filter was built by James Simpson for the East Chelsea Water Co., at London, England. In 1872 a plant was built at Poughkeepsie,

are spoken of as the American method, because this process was developed in this country to meet our special needs. The student should have a clear comprehension of the differences between these two methods.

The water in the slow sand filter passes very slowly through a layer of sand; the filter chokes by the clogging of the superficial layer of sand, and the cleansing of this type of filter is done by removing this layer or *Schmutzdecke*, as it is called. Mechanical filtration, on the other hand, consists in first adding a coagulant such as sulphate of alumina and then passing the water rapidly through a layer of sand.

FIG. 117.—SECTION OF AN ENGLISH FILTER-BED.

The sand is cleansed mechanically by clever devices and by a reversed current of the water.

The slow filtration of water through sand originated as an empiric process imitating nature's method of purifying water as it slowly passes through the soil. It was used before the chemistry or bacteriology of the process was understood. In fact, the intimate processes concerned in slow sand filtration are not yet part of our philosophy. We know that the spaces between the sand are enormous when compared with the size of bacteria; nevertheless, over 99 per cent. of the bacteria are held in the superficial layers of the sand. Nitrification and oxidation of organic matter also take place. The process is not a simple straining,

N. Y., in accordance with plans prepared by Mr. James P. Kirkwood, which was the first practical attempt at purification of a municipal water supply in America.

that is, a simple mechanical filtration. It is a "vital" process in which bacterial activity plays a very large part. The bacteria, algae, and other microorganisms resting upon the upper layer of the sand grow and form a zoögleal mass; each grain of sand becomes coated with a gelatinous and adhesive growth. A continuous layer forms upon the surface a carpet-like mass which constitutes the *Schmutzdecke*. This *Schmutzdecke* effectively holds back the bacteria in the water.

The removal of the bacteria then is largely due to the action of the bacteria themselves, but a visible *Schmutzdecke* is not essential for successful sand filtration. In Hamburg, Lawrence, and other cities a greenish or brownish, slimy *Schmutzdecke* is formed upon the surface of the sand, and gradually becomes so thick and dense as to offer much resistance to the passage of the water itself. The *Schmutzdecke* is then removed. This can readily be done by scraping or shoveling, or by

FIG. 118.—THE ARRANGEMENT OF A SLOW SAND FILTER.

washing the surface sand with special apparatus. Where a visible *Schmutzdecke* is not formed, as in Washington sand filters, it is probable that the microorganisms which form a zoögleal mass do not find favorable conditions for growth. Nevertheless, in this case the surface layer of the sand becomes clogged in the usual manner and the underlying sand is quite clean. The bacteria that escape the surface action are caught upon and stick to the mucilaginous coating of the sand particles, where they perish as in a trap. The experiments of the Massachusetts Board of Health at Lawrence show that filtration may be as effective from a bacteriological standpoint without the visible *Schmutzdecke* as with it.

**Construction and Operation.**—In view of the importance of the subject the student should be familiar with the general principles and some of the details concerning the construction and method of operating a slow sand filter.

It is advisable to let the water settle before it is applied to the sand for the reason that this prevents undue choking or clogging of the filters and thus effects a great economy. One of the main items in the cost of maintaining a slow sand filter is the scraping of the surface layer and the washing of the dirty sand. There are several preliminary methods of treating the water before it is applied to the filter. These methods differ with the character of the water, and consist in the

main of screening, scrubbing, or coagulation. These processes are discussed more in detail upon another page.

A slow sand filter requires an extensive tract of land, for it should be recalled that only two and one-half to five million gallons of water should be filtered per acre per day. The filter should be conveniently located near the community it is to serve, and the high price of urban property is an important economic consideration. Thus, in Washington it requires 21 acres alone for the filter-beds to furnish 63,000,000 gallons of water daily at a 3-million-gallon rate per acre. The settling basins, storage basins for the filtered water, sand-washing apparatus, pumping station, laboratory, and other accessories require considerably more land.

The entire filtering surface is divided into units known as filter-beds. The size of each filter-bed has grown with the development of the art. In the filters recently constructed each bed occupies about one acre. Each bed must be an independent unit, so that the rate of filtration, the cleaning and all other operations may be carried on without disturbing the other beds. The pipes carrying the effluent from each filter-bed must be so arranged that the water may be wasted or utilized. Where the climate is cold, filters should be covered to prevent freezing.

In construction a filter-bed is built very much like an ordinary reinforced concrete reservoir. The bottom and sides must be water-tight, for failure in this regard may be annoying and dangerous for the reason that there may be considerable loss of filtered water or entrance of pollution from the outside if the pressure is reversed. The sides of the bed are usually vertical, although it is of some advantage to make them slanting or with horizontal ledges in order to diminish leaks.

The sand may be obtained from a river bed or from sand banks; the grains should be sharp, hard silicates. If the sand contains clay this should be removed by washing before it is used. It is also important that the filtering sand should be free from lime, which has a tendency to make the water hard. The average diameter of the sand best suited usually varies from 0.2 to 0.3 millimeter. It is especially important that the particles should be mainly of the same size. This is determined by establishing the coefficient of uniformity.

The sand used for filtration contains particles of various sizes; the water is forced around the larger particles and through the finer interstices which occupy the intervening spaces, so that it is the finest portion which mainly determines the efficiency of the sand for filtration. According to Hazen, a provisional basis which best accounts for the known facts considers the size of grain such that 10 per cent. by weight of the particles are smaller and 90 per cent. larger than itself. This is considered the *effective size*, and is determined by sifting a weighed amount of the sand through a series of sieves. Another important point

in regard to the sand is its degree of uniformity; that is, whether the particles are mainly of the same size or whether there is a great range in their diameters. This is shown by the *uniformity coefficient*, a term used to designate the ratio of the size of grain which is 60 per cent. of the sample finer than itself to the size which is 10 per cent. finer than itself.

The usual thickness of the sand layer varies from 12 to 48 inches. The Imperial Board of Health of Germany has fixed 12 inches as the limit below which the sand should never be scraped. The higher limit is advisable wherever practicable. In this country the usual depth of the sand layer is about 3 feet, and this is reduced by successive scrapings for the purpose of cleaning until it approaches 12 inches, when the sand is replaced. A thick sand layer has a steadying action upon the water on account of the increased friction, and thus aids in preventing irregularities in the rate of filtration.

The sand rests upon a stratified layer of rock and gravel laid in graded sizes which supports it so that it does not work its way down into the underdrains.

The size, position, and nature of the underdrains are a very essential part of the construction of a slow sand filter. The underdrains must be set so that the rate of filtration will be the same in all parts of the filter. If this part of the apparatus is not properly designed in a filter-bed having the broad expanse of an acre the water may pass through the sand in certain portions at the rate of ten or more million gallons while it may be found that at other portions there is practically no flow at all.

The depth of the water above the sand is usually 3 feet. In European filters the depth varies from 3 feet to 52 inches. It is comparatively easy through simple mechanical devices to regulate the flow of the applied water so that the depth of the water above the sand will remain uniform.

Probably the most important factor in the operation of a slow sand filter is the rate of filtration. The tendency has been gradually to reduce the rate during the past thirty years. In this country slow sand filters are usually run at a rate of about 2,500,000 to 3,000,000 gallons per acre per day. Three million gallons is the maximum rate commonly allowed. During times of stress, however, or for other reasons, the rate is sometimes speeded up to five or six million gallons per acre daily. In Hamburg the filters are not allowed to run faster than 1,600,000 gallons, and in Berlin 2,500,000 gallons. Water passed through sand at the rate of 4,800,000 gallons per acre daily has a vertical movement of 3.94 inches in an hour. When the rate is 2,400,000 gallons the vertical motion is 1.97 inches per hour, and when the rate is slower the vertical motion is correspondingly diminished. It will

thus be seen that this process is well named in that the water passes very slowly through the filter. This is of fundamental importance because the hour or more during which the water rests upon the surface of the sand and passes through the superficial layer is the critical time when the bacteria are enmeshed in the *Schmutzdecke* or adhere to the particles of sand and the other biological and chemical processes take place. The tendency of engineers is to increase the rate of filtration on account of the evident economy; the tendency of sanitarians is to diminish it so as to keep well within the factors of safety. If hypochlorite or chlorin is added to the filtered water there is no objection to speeding up the rate of the filter. The rate of filtration may be governed by automatic devices or may be controlled by hand by simply regulating

FIG. 119.—DIAGRAM ILLUSTRATING  
"LOSS OF HEAD."

the valve which governs the pipe carrying the effluent from each filter-bed. The friction of the sand layer varies from time to time, so that careful attention is required in order to maintain a steady flow and a constant rate, which is essential, for sudden variations in rate are fatal to the successful purification of water by the slow sand process.

The friction of the sand is measured by the loss of head. The loss of head is the difference between the level of the water above and below the sand layer measured in water gauges. This loss represents the friction or resistance of the sand layer. It greatly increases as the filter clogs up. When a filter is new or perfectly clean the loss of head is usually about 0.2 foot or less; when it exceeds 4 feet the rate of filtration cannot be maintained at 3,000,000 gallons per acre daily with the devices provided, and the filters must be cleaned.

The length of time a filter may run before the loss of head becomes so great that it becomes unprofitable and requires cleaning varies from a few days to many months. The time depends upon the character of the water, the rate of filtration, and temperature, the formation of the *Schmutzdecke* and many other factors. In cleaning a filter it is sufficient to scrape off only enough sand to a layer that appears clean. As a rule the sand immediately below the surface is not apparently soiled, and usually it is not necessary to take off more than an inch or so of the surface layer. This sand is removed to special cleaning devices, where it is thoroughly washed with filtered water and then stored in bins and replaced when the sand layer reaches a depth of about 12

inches. The *Schmutzdecke* and the surface layers of the sand are usually removed by hand with broad shovels. There are also mechanical devices which accomplish the same purpose. After cleansing, the effluent from a filter-bed should be wasted until the bacteriological examination shows that the filter is again performing efficient work. This may require several days, the time varying with the temperature and other conditions.

**Efficiency and Control of Slow Sand Filters.**—The efficiency of a slow sand filter is mainly measured by a comparison of the number of bacteria in the raw and filtered water. A good filter should eliminate at least 99 per cent. of the bacteria, provided the applied water is grossly polluted. In any event the filtered water should not contain over 100 bacteria per cubic centimeter and very few colon bacilli. It is to be noted that all the bacteria in the filtered water do not represent those that actually pass through the sand. Some of them grow in the underdrains and gravel layer and are, so far as known, harmless varieties.

In Germany the rate of filtration and other factors are minutely regulated and controlled by official ordinances. In this country the operation of the filter is usually left to the individual caprice of the engineer in charge.

New Jersey has recently (August, 1918) passed a law requiring the examining and licensing of operators of water and sewage treatment plants, under the direct control of the State Department of Health. This appears to be pioneer legislation of this kind in this country.<sup>2</sup>

A slow sand filter cannot be effectively operated without skilled superintendence of an engineer expert in the art of water purification. It also requires a small laboratory with a competent bacteriologist, who must make daily observations of the applied water and the effluent from each filter. The effluent from a filter not giving good results should be wasted. The water from a new filter, or one just scraped, should not be used until the bacterial results show that it is accomplishing effective purification.

There are many ways by which a better effluent may be secured, such as the use of lower rates of filtration, finer grained filtering materials, and more complete preliminary treatment, such as settling basins, storage, or chemical coagulation. The filtered water may be further purified with hypochlorite of lime, chlorin, ultraviolet rays, or ozone. It requires a surprisingly small amount of hypochlorite practically to sterilize a filtered water. In Pittsburgh 0.13 part of bleaching powder (measured as available chlorin) per million parts of water is sufficient for this purpose.

<sup>2</sup>The need for expert supervision was recently shown by the occurrence of an epidemic of typhoid fever at Xenia, Ohio. The city's drinking water was treated with bleach, and therefore was considered safe. It developed on investigation that the hypochlorite used had a chlorin content lower than specified.

Because slow sand filtration has achieved such marked success with some waters and greatly reduced the amount of typhoid is no reason why it should be universally recommended under all circumstances. To recommend slow sand filtration in all cases would be as irrational as to recommend the use of antitoxin in every case of sore throat. A correct diagnosis is essential. Every water cannot be successfully or economically treated by this process alone. Thus, the very turbid waters of our South and West contain particles of clay so fine that they pass a sand filter. No amount of sand filtration will take out some of these particles. The Potomac water in times of high turbidity may be passed through a sand filter three or four times without removing the residual turbidity due to these microscopic particles. To apply a very turbid water to a sand filter soon chokes it and adds unnecessarily to the difficulty and expense of the process. The particles may be so fine that they will not all settle even when the water is given long storage. There are several ways of solving this problem, which is of first magnitude for the purification of the surface water of a large part of our country. One of the best ways is to provide large storage reservoirs, so that the water may be taken from the river only at favorable times, rejecting the flow during periods of high turbidity. Another is to use preliminary coagulation with aluminium sulphate and provide for sedimentation before applying the water to the sand. Much of the turbidity may be removed by a rapid preliminary filtration through some coarse material such as charcoal, sponge, etc. This process is known as scrubbing. No general rule can be set down. Waters differ radically, and the same stream varies from time to time. Each problem must be studied and solved in relation to its own special condition. Whether the filtered water should be further purified with bleaching powder, chlorin, ultraviolet rays, or ozone depends upon circumstances.

**Results of Slow Sand Filtration.**—The cities listed in the table on the following page purify their water supply by slow sand filtration.<sup>3</sup>

The good results of purifying water by the slow sand method have been abundantly demonstrated in Altone, near Hamburg, in 1892, during the cholera epidemic; also in Hamburg since 1893 and in Lawrence also since 1893; further in Albany, Philadelphia, Pittsburgh, Berlin, Paris, and many English cities. It should be noted especially at Albany that the typhoid rate did not come down immediately after filtration. It sometimes requires one or two years to reach the residual or "normal" rate. In a few instances, such as Washington, D. C., and Youngstown, O., filtration of the water was not followed by a noticeable diminution in the typhoid rates, presumably due to the fact that little of the typhoid fever in these places was water-borne.

The best results in water purification, as measured by the improve-

<sup>3</sup> List furnished by Allen Hazen, March 31, 1920.

ment in the health and reduction of the death rate among those who use the water, have been obtained with slow sand filters. Hazen believes that this is probably because the method is an old one, has been long and carefully studied, and has been applied on a large scale in well-perfected forms for many years, rather than to any natural superiority of the method.

The purification of water through slow sand filtration not only diminishes the amount of typhoid and other water-borne intestinal infections, but is believed also to reduce the general death rate. This fact, known as the Mills-Reinecke phenomenon, is discussed on page 1148.

**Mechanical Filters.**—The essential and characteristic features of mechanical filtration are: (1) The addition of a chemical precipitant or coagulant to the water, and (2) then passing the water rapidly through a layer of sand. These are either the gravity or the pressure type. The filtering sand is contained in a large wooden, iron, or concrete tank so arranged that it can be mechanically washed.<sup>4</sup> These filters are well named, not only because the filtering sand is washed mechanically, but because the action is more strictly a mechanical strain-

<sup>4</sup>Mechanical filters date from 1884, when the process was patented by J. W. Hyatt and Professor Albert R. Leeds. They were first used municipally at Somerville, N. J., in 1885. The Hyatt patent expired in 1901, and since then numerous improvements in details have been made and patented, considerably improving the art of cleaning water through this process.

ing, whereas biological processes are the main features in the purification of water passing through a slow sand filter.

*Washing the Filters.*—The filters are washed by a reversed flow of water. The sand may be agitated by compressed air; originally revolving rakes were used in small installations. When a “high velocity wash” is provided, as is usually the case, twenty gallons or more filtered water per square foot of filter per minute is forced in a reversed direction through the sand. This rate provides sufficient force to “boil” the sand, at the same time ridding it of retained coagulum. Low velocity washing occasionally used in conjunction with compressed air saves filtered water. This requires filtered water to the extent of 5 per cent. of the total daily pumpage.

It has been found that the periods of operation in some instances can be more than doubled by shutting the effluent valve to allow air and gases entrained in the sand to rise, or by slowly passing filtered water back to drive it out without disturbing the sand.

**Coagulants.**—The *coagulants* commonly used are sulphate of aluminium, sometimes alum, occasionally sulphate of iron. The alkaline carbonates present in the water decompose the aluminium sulphate with the formation of aluminium hydroxid, which is thrown out of the solution as a flocculent, colloidal, jelly-like precipitate. The reaction is as follows:

Calcium bicarbonate is necessary to break up the alum, and if not normally present in the water some lime or soda must be added. The reactions and methods of estimating the quantities are given in detail on page 1141. The precipitated aluminium hydroxid clears the water very much as white of egg clears coffee. Suspended matter, including bacteria and inorganic particles, are enmeshed and deposited on the surface of the sand. Thus it will be seen that an artificial inorganic *Schmutzdecke* is produced upon mechanical filters instead of the natural organic *Schmutzdecke* of the slow sand filter-bed. When this deposit becomes abundant enough to clog the filter the filter is washed by reversing the flow and mechanically agitating the sand.

It is advisable to provide coagulating basins to hold the water for a short time after it has received the coagulant, in order to allow the chemical reaction resulting from the treatment to take place. Such basins also serve to remove by sedimentation much of the precipitate, and the filters therefore do not clog so readily, and cleansing is not required so frequently.

The rate at which water is passed through mechanical filters is very great when compared with slow sand filters. Rates varying from 125,000,000 to 175,000,000 gallons per acre per day are used.

One hundred and fifty million gallons per acre daily may be taken as a fair average of what is to be expected of them. On account of the rapid rate of filtration there is great economy of space. However, while the mechanical filters are cheaper when first cost is considered, the advantage is with slow sand filters as far as cost of maintenance is concerned.

The proper amount of coagulant is added to the water by means of a small automatic measuring apparatus. It requires, as a rule, about one or two grains of alum or sulphate of aluminium for each gallon of water to be treated. The amount of alum added to the water must vary from time to time, depending upon the turbidity, the reaction, and also upon the amount of calcium carbonate in the water. The turbidity and composition of many of our streams vary suddenly and require a watchful eye. If too little alum is added the effluent will not be clear; if too much is used the effluent will contain the excess of alum in solution. Mechanical filters, therefore, require intelligent and constant supervision in order to furnish satisfactory results.

Mechanical filtration meets with special favor in this country because it affords a comparatively cheap method of supplying a clean-looking water from a very turbid source. The process is particularly applicable to the muddy streams of our South and West. In fact, it is the only known method of rendering some of these waters quite free of turbidity.

Mechanical filters, when properly manipulated, will take out most (from 95 to 99 per cent.) of the bacteria contained in the raw water. The bacterial purification, however, is not as constant and uniformly high as that obtained by slow sand filtration. The aluminium hydroxid also takes out much of the soluble coloring matter which the water may contain, as well as its turbidity.

Judged by the effects upon morbidity and mortality, mechanical filtration of water alone has in no instance given the same satisfactory results afforded by slow sand filtration. Most of the older mechanical filters in use in America fell short in hygienic efficiency. This was especially true with the old and inferior plants which often were without skillful supervision.

In 1900, according to Hazen, 1,860,000 people, or 6.3 per cent. of the urban population of the United States, were being supplied with filtered water. In 1904 the number of people so supplied had increased to 3,160,000, or 9.7 per cent. of the urban population of the country. Since that time many large cities have installed filter plants, until (1913) about 8,000,000 people, or over 20 per cent. of the urban population, were being served with filtered water. Most of this filtered water is now also treated with bleaching powder or chlorin.

THE DIFFERENCE BETWEEN SLOW SAND AND MECHANICAL FILTRATION

<i>Slow Sand Filtration</i>	<i>Mechanical Filtration</i>
English system or English filter-beds—originated in England.	American system — developed in America to meet our special needs.
Has been long in use and effectiveness is established.	Comparatively recent (since 1884), and hygienic effectiveness not fully established.
Preliminary treatment not an essential part of the process, though sometimes desirable.	A coagulant is first added to the water—sulphate of aluminium, alum, or sulphate of iron.
Water passes slowly through a layer of sand, in large, shallow, tight reservoirs.	Water passes rapidly through a layer of sand in small wooden, concrete, or iron tanks.
Usual rates from 1,600,000 to 5,000,000 gallons per acre per day.	Usual rates 100 to 200 times as rapid—100,000,000 to 175,000,000 or more gallons per acre daily.
Cleaned by scraping surface layer of sand— <i>Schmutzdecke</i> .	Cleaned by reversed flow of water and mechanical agitation of the sand—hence the name “mechanical” filtration.
The process is mainly biological, partly a mechanical straining. Duplicates nature’s process of purifying water.	The process is mainly a mechanical straining. An artificial imitation of nature’s process.
Partial oxidation of nitrogen compounds.	Chemical indices of pollution not affected.
First cost is large; maintenance comparatively small.	First cost is comparatively small; maintenance large.
Especially serviceable for water having little turbidity.	Especially suitable for turbid waters, containing silt and clay.
Removes about 20 per cent. of the coloring matter.	Takes out nearly all of dissolved coloring matter.
Removes about 99 per cent. of the bacteria; action is uniform.	When properly operated removes from 95 to 99 per cent. of bacteria—less uniform.
Favorable effect upon health demonstrated.	Hygienic efficiency not established, but doubtless would be more satisfactory if well operated.

**Recent Tendencies in Water Purification.**—The development of water disinfection with chemicals (bleach or chlorin) has lessened the importance of filtration as a sanitary safeguard. Chemical disinfection invariably follows filtration; that is, filtration is now used to render the water clean, disinfection to render it safe. Filtration is now used mainly to remove turbidity and color; chemicals are used to kill typhoid and other bacteria. The sanitary importance of filtration, therefore, is

The following is a partial list compiled by Hazen of places in the United States where mechanical filters are in use:

Place	Population 1910	Capacity of Filters in Gallons per Day
Cincinnati .....	363,591	112,000,000

And about 250 smaller plants.

lessened, where reliance is placed on chemical disinfection. For these reasons, sand filters are speeded up. This tendency has an element of danger, for the factor of safety in many municipal water plants is now very small. Accidents happen with dire results.

Nearly all of our large cities have adopted filtration or chlorination or both. Boston is practically alone at present in supplying an unfiltered, untreated water. The most notable recent developments in municipal water supplies may be found in impounded and gravity supplies. New York City proposed to add a rapid sand filter of 320 million gallons per day to the Croton supply. Los Angeles uses a mountain stream 250 miles away for her drinking water, while the Hetch-Hetchy project for San Francisco is 175 miles distant from that city.

**Household Filters.**—The domestic filter as ordinarily used in the household has limited sanitary value. The purification of water, even by so simple a method as straining, requires a degree of care, knowledge, and experience that is not found in the kitchen. If a water is infected, reliance should not be placed upon any household filter operated in the usual way. It is possible in the laboratory by the use of special precautions to pass water through a Pasteur-Chamberland or a Berkefeld filter so as to obtain a sterile filtrate. This requires skilled bacteriological manipulation of a kind that cannot be attained in ordinary service in the house. I have seen janitors "clean" a filter in such a way as to actually contaminate the water.

There are two main types of household filters: one made of unglazed porcelain (kaolin), known as the Pasteur-Chamberland, and the other made of diatomaceous earth, the Berkefeld, or Mandler. Even in the closest grained unglazed porcelain filter the pores of the filter are larger than the bacteria. The bacteria do not get through on account of the tortuous passage; they adhere to the particles that make up the filtering substance. But if conditions are favorable, bacteria, such as typhoid, may soon grow through its walls. The Berkefeld or Mandler filters of diatomaceous earth are more porous than the Pasteur-Chamberland filters.

When a water is not infected, but turbid, household filters are serviceable in rendering it clear. They are specially useful when the turbidity is due to clay or to iron, or other inorganic particles that may readily be removed by simple straining.

The sanitarian places no reliance upon the filtration of water in the household, and for drinking purposes such water, if infected, or suspected, should be boiled. The boiling should be the last process.

Filters of natural stone, charcoal, asbestos, and a great variety of porous substances are on the market for domestic use. These filters may be useful in cleaning water that is turbid, but they cannot be depended upon to purify an infected supply.

**Scrubbing or Roughing Filters.**—Scrubbers are rapid coarse-grained filters through which turbid water is passed at a very high rate in order to remove coarser particles and some of the turbidity. This process of scrubbing the water is principally used as a preliminary to sand filtration. It is designed to protect the sand filters from clogging up too quickly and thus economize the operation. Scrubbers, also known as roughing filters, consist of some porous substances such as sponge, coke, and lava. The principal difficulty connected with a scrubber is an efficient and economical device for cleaning them, which must be done at frequent intervals.

**Screening.**—Screening or straining is used particularly to remove fish and floating leaves, sticks, etc. Screens may consist of steel bars arranged so that they may be easily raked off, or of wire cloth arranged in pairs, so that while one screen is raised for cleaning its mate is below in service. Revolving screens are efficient. The motion should be continuous, and the cleaning is done on that part of the screen above the water by jets of water playing upon it. Screening is of no service in removing algae or microorganisms, and can only be depended upon to remove the coarse particles, and is only necessary where the water contains such material. Thus, St. Paul uses a motor-driven rotary screen of 80 mesh monel metal to eliminate vegetable and solid matter in its lake-water supply.

## STORAGE

The storage of water is one of the simplest and best means of purifying it. The first cost may be large, but the cost of maintenance is comparatively trifling. Harmful bacteria soon die in a stored water, the solid particles settle out, the organic matter is largely oxidized, the color is gradually bleached, and other improvements take place. Storage takes advantage of many of nature's methods of purifying water, viz., time, sunlight, dilution, sedimentation, oxidation, and antibiosis.

A stored water may deteriorate in quality owing to the growth of algae and the decomposition of organic matter. Algae and diatoms grow in stored water exposed to sunlight, particularly in warm weather. While these organisms are not harmful, they impart disagreeable tastes and odors to the water. See page 1050. The decomposition of the organic matter in a storage water may also cause unpleasant tastes and odors, especially at the spring and fall overturn. See page 1031. Waters stored in a closed reservoir keep without deterioration, and the advantage is therefore manifest. Filtered water should always be stored in covered reservoirs, not only to protect it from strong light, but also to prevent contamination from dust and other sources.

## SEDIMENTATION

Sedimentation is of limited use in improving the sanitary quality of a water. Sedimentation basins are frequently used as a preliminary process in water purification. It is the cheapest way of removing relatively large particles which will settle out in a moderately short time. There is also a sanitary advantage in that the suspended particles mechanically carry down with them some of the bacteria. The water, as a rule, does not remain in the sedimenting basins long enough to obtain the full effects of storage.

Sedimentation is a very important factor in the bacterial purification of flowing streams. The effect of sedimentation is most manifest when the flow of water is rapid enough to prevent accumulation, at any point, of the products of bacterial multiplication, but not so rapid as to interfere with a comparatively rapid action of gravity. Turbid streams purify themselves through sedimentation more quickly than clear streams, owing to the washing or scouring action of the particles as they fall through the water.

## CHEMICAL METHODS OF PURIFYING WATER

Methods for chemically purifying drinking water include the use of lime, ozone, permanganate of potash, various metals and their salts, and chlorin and its compounds the hypochlorites. Other methods have employed hydrogen peroxid, barium peroxid, peroxid of chlorin ( $\text{ClO}_2$ ) and bromin and chlorin together.

**Ozone.**—Ozone, discovered by Schönbein in 1840, is one of the most satisfactory methods of purifying water from a sanitary standpoint. As a germicide it is the most effective of all the methods used except boiling. A ozonized water is practically sterile and the organic matter is partially oxidized. It is true that a few resisting spores are not killed, but they are harmless when taken by the mouth. The limitations of the ozone process are that it does not clarify the water in any way, and that it has practically no effect upon the mineral salts. From a practical standpoint the expense of producing ozone in sufficient concentration is disproportionately large, but this is an electrical engineering problem which is showing encouraging advance.

As a general rule it is not desirable to add ozone to a dirty or turbid raw water. It is better first to clarify the water by some method before applying the ozone. The quantity of ozone required for effective bacterial action depends upon the amount of organic impurities contained in the water. Some German plants have an average consumption

of 1.3 g. of ozone per c. c. or about 10 pounds per million gallons. Much of the ozone is used up by the organic impurities, and this may happen so rapidly that it will not have a chance to act upon the micro-organisms.

An impure water containing much organic pollution treated with ozone may give disappointing results, from the fact that unpleasant flavors may be developed. These are doubtless due to the partial oxidation of the decomposing organic matter with the production of nitrogenous compounds not well understood.

FIG. 120.—AN OZONIZER.

A. Open tube through which air is led. B and C are electrodes, separated by the glass tubes D, between which the current of air passes. (After McPherson and Henderson's "A Course in General Chemistry," published by Ginn and Co., Fig. 13, p. 31.)

For the purification of water, ozone is produced by electrical discharges in the atmosphere, and this ozonized air is then brought into intimate contact with the water. To produce the ozone requires a silent brush discharge and the air must be cold and free of moisture. If sparking occurs between terminals, oxids of nitrogen are formed which are corrosive and prevent the formation of ozone. The ozonizing apparatus therefore must be carefully designed, and its operation needs skilled supervision.

An ozonizer consists of two conducting metallic surfaces separated by a dielectric, such as glass or mica, and so constructed that a current of air may pass between the two conducting surfaces.

Fig. 120 represents a common form of ozonizer. Oxygen or air enters at A and follows the course indicated by the arrows. The conducting surfaces B and C are separated by a glass dielectric D. Wires leading from an induction coil are connected with B and C. As the oxygen passes upward between the conducting surfaces it is subjected to the influence of the electric discharge, and a portion of the element is thereby changed into ozone. The air passing between the electrodes must be dry, otherwise peroxid of hydrogen will form at the expense of the ozone. It is therefore customary first to dry the air by refrigeration or by passing it over unslaked lime before it enters the ozonizer. The temperature of the air in the ozonizer must not go above a certain degree, else ozone will not be formed. The maximum production of ozone takes place at about 25° C. Overheating may be prevented by a water jacket in contact with the electrodes. The voltage must be high—from 8,000 to 20,000 volts; that is, the current must have a small volume, but high potential. Ordinarily only a very small percentage of

the oxygen is transformed into ozone. Recently, however, Harries has obtained a yield of from 18 to 19 per cent. by means of an improved ozonizer.

The molecule of ozone ( $O_3$ ) readily gives up one atom of this gas in a nascent condition. It therefore has a very strong oxidizing action upon organic matter, decolorizes many pigments, especially of vegetable origin, and has a very powerful germicidal action. In this respect the action of ozone corresponds chemically to potassium permanganate, the hypochlorites, and other powerful oxidizing chemicals used in water purification.

FIG. 121.—AN INSTALLATION FOR TREATING WATER WITH OZONE

A. Settling tank. B. Filter. C. Storage reservoir for filtered water. D. Tower, water enters above and ozone below. E. Pure water reservoir. F. Ozonizer. G. Dryer, to remove moisture from air before it passes into ozonizer. H. Fan.

It is necessary to get any excess of ozone out of the water in order to avoid the corrosion of pipes. This may be done by aëration, by means of fountains or cascades. On account of the insolubility of the ozone, it soon disappears. The fact that ozone is largely insoluble in water makes it necessary to bring it into intimate contact with all portions of the water to be treated. This is usually accomplished by allowing the water to trickle downward through tall cylinders filled with coke, lava, or other similar substances while the ozone is admitted to the bottom of the cylinder. The water flows downward, the ozonized air works its way upward, and in that way the desired contact is obtained between the ozone and every portion of the water.

A very small amount of ozone is effective for the purification of water. It only requires from 1 to 3 milligrams per liter. The modern machines produce concentrations as high as 10 grams and more of ozone per cubic meter of air. The ozone not taken up by the water

may be used over and over again. This is accomplished in some of the ozonizing processes by conducting the air that leaves the upper part of the water cylinder back to the ozonizer.

In general, it may be said that, owing to the expense and the electrical and engineering difficulties involved, the ozonizing process is not at present applicable to the purification of water upon a small scale. It has been applied with success upon a large scale in a number of places. The first ozonizing apparatus for the purification of water on a large scale was installed by Siemens-Halske at Lille, France. Other ozonizing plants for purification of drinking water have been installed at Wiesbaden and Paderborn in Germany; Cosne, Chartres, Nice, Denard in France; Ginnekin in Holland; Sulina on the Black Sea, and Petrograd in Russia; Lindsay, Ontario; and Paris, in part, 24,000,000 gallons per day from the River Marne. In France there are 26 large municipal plants where ozone is used. At Lindsay the ozone treatment failed because the ozone and the water were not properly mingled. At Wiesbaden much trouble was caused by the oxidation of the iron. Experiments at Ogdensburg, N. Y., failed to remove the color of the water. Where water power may be obtained for the generation of the electricity necessary to produce the ozone the cost is very much lessened. The principal systems at present used for ozonizing water are the Siemens-Halske, the Gerhard, Tindal, De Frise, Otto, Abraham Marmier, Vosmaer, Bridge, Stynis, and others.

Ozone treatment is best adapted to sewage-polluted waters, the appearance of which is satisfactory. Waters of turbid streams are least suited to this treatment. Ozone must now compete with bleaching powder, which has nearly the same effect and is cheaper and simpler. One objection to the treatment of water by ozone is that the electric apparatus is delicate and complicated and requires skilled attendance. The ozone processes are not yet standardized; at present it is difficult to determine what waters may best be treated with it.

**Chlorinated Lime—Bleaching Powder or “Chlorid of Lime.”**—Chlorinated lime, popularly miscalled “chlorid of lime,” and often spoken of as “bleach,” has for years been used to disinfect sewage, outhouses, cellars, and for miscellaneous purposes. The first recorded use of hypochlorite was by Houston in 1905 at Lincoln, England, where the sodium salt was employed. Its use in the disinfection of water as a practical process in the United States dates from 1908, when Mr. G. A. Johnson was called to solve the serious and difficult problem in water purification at the Chicago stock yards, the discharges from which entered Bubbly Creek. Filtration of the water of Bubbly Creek was not satisfactory, and all methods failed to abate the nuisance until Mr. Johnson treated the water with chlorinated lime. The method further attracted widespread attention by the Jersey City Water Company in essaying to

comply with its contract to furnish pure water to Jersey City by simply adding a little bleaching powder. Other municipalities soon took it up in order to render their public water supply safe, until now it is used by most cities and towns throughout the country.

*Properties.*—Chlorinated lime is made by saturating slaked lime with chlorin at ordinary temperatures. It is a white or whitish powder occurring also in friable lumps; dry or slightly damp, with a feeble odor of chlorin and a disagreeable, bitter, and saline taste. It has an alkaline reaction, but finally bleaches litmus paper. The medicinal dose administered by the mouth is from one to five grains (gram, 0.06—0.3). As a mouth wash a one per cent. solution may be used. The physiological action of chlorinated lime resembles that of chlorin with the super-added causticity derived from the lime in its composition. Externally it is an active irritant and sometimes moderately caustic.

A 6 per cent. solution in water may be made. However, all the constituents of bleaching powder are not soluble. Chlorinated lime contains a large amount of calcium hydroxid ( $\text{Ca}(\text{OH})_2$ ) which is largely insoluble, hence the milky appearance of the solution, and also the precipitate known as "sludge," which settles rapidly. The calcium oxychlorid, and also calcium hypochlorite, the active principles in chlorinated lime, are readily soluble in water.

Upon exposure to the air the hypochlorites deteriorate rapidly to the more stable and inert carbonates. Great care must therefore be taken to keep the substance in air-tight containers and to know the correct amount of available chlorin in each lot of the bleach at the time it is used.

*Composition.*—The precise chemical constitution of chlorinated lime is not definitely known, although the matter has been frequently investigated. It seems quite certain that neither chlorid of lime,  $\text{CaCl}_2$ , nor hypochlorite of lime,  $\text{Ca}(\text{OCl})_2$ , exists as such in dry bleaching powder, but is formed on dissolving it in water. Calcium oxychlorid,  $\text{CaOCl}_2$ , is now generally accepted to be the essential agent of *dry* bleaching powder, and calcium hypochlorite,  $\text{Ca}(\text{OCl})_2$ , to be the active germicidal principle of the solution. Thus:

Calcium chlorid which is thus formed, or calcium carbonate, which forms when bleaching powder is exposed to carbon dioxid, are both inert so far as germicidal value is concerned.

*Modes of Action.*—When bleaching powder is added to water, the reactions taking place are complex. The germicidal action is due at least to three factors: (1) the nascent oxygen formed; (2) the free and liberated chlorin; and (3) chloramins which are formed from

organic matter in the water. The hypochlorites are themselves directly toxic.

(1) *Nascent oxygen* is a very powerful germicide; it is liberated from the hypochlorous acid.

(2) *Chlorin* is a potent germicide. There is always some free chlorin in bleaching powder. Chlorin is also liberated when the hypochlorous acid decomposes, thus:

The intimate nature of the chemical processes is somewhat involved, but it is plain that hypochlorous acid and its salt, calcium hypochlorite, both liberate free chlorin, especially in acid solutions.

That chlorin itself acts as a germicide in water is evident from the fact that liquid chlorin gas has about twice the effect of the same amount of chlorin in bleaching powder. Further, water free of organic matter (except bacteria) can be sterilized with minute amounts of chlorin, before this element has combined chemically with  $\text{H}_2\text{O}$ .

(3) *Chloramins*. Hypochlorites in contact with ammonia form chloramin,  $\text{NH}_2\text{Cl}$ . Hypochlorites in contact with amino-acids also form chloramins, most of which are germicidal, some of which have extraordinary potency. Dakin and Cohen examined a number of chloramins, and found dichloramin-T to be particularly active.

Rideal added chlorin to water and found that when all the chlorin is consumed, there remains a strong germicidal action. It was also found that ammonia added to water with bleaching powder increases the activity of the hypochlorite. Dakin attributed the persistent action to the formation of chloramins, by reaction of the hypochlorites on protein or amino-acids. Dakin and Dunham studied the disinfection of water and found that adding citric, tartaric, acetic and similar organic acids increases the activity of chloramin-T. The compounds thus formed are unstable but benzoic acid produces a relatively stable compound with chloramin-T which is sold as *Halozone* (p-sulphon-dichloramin-benzoic-acid). It destroys typhoid bacilli in thirty minutes in dilutions of 1 part to 300,000 parts of water. For further discussion of chloramins, see page 1417.

It will thus be seen that chlorin itself, nascent oxygen and also chloramins take part in the disinfecting action of bleaching powder. The relative part played will vary with the amount of organic matter contained in the water. It is theoretically conceivable that the liberated chlorin will directly kill a typhoid bacillus by combining with the

protein of the germ, and the chloramin thus formed may kill another typhoid bacillus.

**Strength.**—The amount of hypochlorites added is usually expressed in terms of “available chlorin,” although in reality this represents the available oxygen liberated by the chlorin. Thus a good bleaching powder will average 35 per cent. of available chlorin, which is the equivalent of about 7.9 per cent. of available oxygen. By available chlorin is understood the chlorin readily liberated from its combination as determined by the usual thiosulphate titration.

*How to Dissolve Chlorinated Lime.*—Chlorinated lime is soluble in about twenty times its weight of water, leaving an insoluble residue consisting mostly of calcium hydroxid,  $\text{Ca}(\text{OH})_2$ . Half a pound of chlorinated lime may be dissolved in a gallon of water. Such a solution contains approximately 6 per cent. by weight of chlorinated lime, representing about 2 per cent. of available chlorin.

To obtain a clear solution of chlorinated lime it is important to remember that the available chlorin is readily soluble, even in fairly cold water, and the undissolved sludge of calcium hydroxid, silica, etc., settles readily. Settling, at least, takes place readily if a few simple rules are observed. (1) Do not mix too stiff a paste, otherwise a gelatinizing action takes place and greater difficulty in settling is encountered. (2) Never mix a paste with less than one-half a gallon of water for one pound of chlorinated lime. (3) It is not necessary or desirable to grind up or break up the lumps too thoroughly; the available chlorin nearly all dissolves readily, and too much agitation is detrimental to prompt settling. With these points in view a stock solution containing approximately 2 per cent. of available chlorin may be made as follows:

Three hundred pounds commercial chlorinated lime (35 per cent. available chlorin) = 105 pounds of available chlorin, assuming a recovery of 100 pounds of this free from sludge. These 100 pounds must be contained in 600 gallons to give a clear 2 per cent. solution. Due allowance must be made for proper washing of the sludge, for it contains, in addition to the suspended lime and silica, a solution of equal strength to that of the clear liquid. The amount of sludge is equivalent to about one gallon for each five pounds of chlorinated lime used.

*Method of Dosing.*—While the chlorinated lime treatment of water supplies is essentially simple, yet it requires able professional supervision; disappointing results will come from haphazard work. The great essential is a uniform dosing of a standard solution.

Economical working makes it desirable to use two tanks, each equipped with agitators and a looped chain as a drag along the bottom. These tanks should be made of concrete, or at least lined with cement, and adjustable means provided for drawing off the clear liquor from above, as well as an outlet for removing the sludge at the bottom.

Assuming that two 700-gallon tanks are provided, and that 300 pounds of chlorinated lime giving 600 gallons of clear 2 per cent. solution are to be prepared in each tank at one mixing, the procedure should be as follows:

Into tank No. 1, which is empty, is drawn 200 gallons of weak wash water from tank No. 2.

Then 300 pounds of chlorinated lime is dumped into the tank and mixed for one-half hour.

The tank is now filled to a mark indicating 660 gallons with the remaining wash water from tank No. 2, which does not have to be particularly clear.

This is now allowed to settle for at least 8 hours and preferably over night, when 600 gallons of clear solution will be ready to draw off to the stock tank. There will remain about 60 gallons of sludge which requires washing to obtain the remaining available chlorin. The agitator is now started in tank No. 1, which is filled to the 660-gallon mark with water, and then allowed to settle. This wash water is used in making up the next batch in No. 2 tank; the now practically exhausted lime sludge in tank No. 1 is thrown away.

The standard stock solution thus prepared will contain available chlorin equal to  $\frac{1}{2}$  pound of chlorinated lime per gallon, or about 2 per cent. available chlorin, or 6 per cent. of chlorinated lime by weight. Hence an average clear water requiring 8 pounds of chlorinated lime per million gallons will require 16 gallons of this standard solution per million gallons of water. This is a trifle less than 1 drop of this solution containing 2 per cent. of available chlorin in a gallon of water.

The table on the following page covers the range of chlorinated lime ordinarily used in water purification, and may be found useful for comparison.

*Amount Used in Water Purification.*—The remarkable germicidal power of chlorinated lime is better understood when it is known that 3 grains of a practically harmless substance will kill myriads of bacteria contained in a barrel of water. Ordinarily the amounts used are from 1 to 2, or 5 parts in terms of "available chlorin" per million gallons of water. In practice the actual amount used in water purification is from 5 to 12 or more pounds of bleaching powder per million gallons of water. The bleach cannot be detected by the sense of taste provided the amount does not exceed 25 pounds.

The amount of chlorinated lime necessary to add to a water in order to accomplish satisfactory results varies with the composition of the water. In general, the more organic matter the water contains the more bleaching powder is necessary. This is for the reason that some of the bleaching powder is used to oxidize the organic matter before it can produce its germicidal action. A bacterial reduction of 99 per cent.

may be obtained in a water containing little organic matter with 1 part per million, whereas it requires up to 40 parts per million in sewage to affect a similar bacterial reduction; and still more for feces in a bed pan or cesspool.

New York used 16 pounds per million gallons; Omaha, 7½ pounds per million gallons after coagulation and sedimentation; Cincinnati, 5 to 12½ pounds; Toronto, 6 pounds; Montreal, 5 to 7½ pounds; Cleveland, 16 pounds; Erie, 7 to 10 pounds; Milwaukee, 6 pounds; Pittsburgh, 3 pounds after slow sand filtration; Jersey City, 5 to 8 pounds; Council Bluffs, 15 pounds following the alum precipitation; Nashville, 14 pounds. Bleaching powder was also used to purify the public water supplies of St. Louis, Minneapolis, Chicago, Brainerd, Minn.; Ridgwood, N. J.; Corning, N. Y.; Grand Rapids, Mich.; Little Falls, N. J.; Harrisburg, Pa.; Baltimore, Md.; Niagara Falls; Toronto; Ottumwa, Ia., and many other places. Some of these cities have recently changed from bleaching powder to chlorin gas.

Clark and Gage found that 0.1 part of available chlorin per 100,000 effected a satisfactory purification of the Merrimac River water; that is, results were obtained equal to slow sand filtration. *B. coli* was entirely eliminated. They discovered the interesting fact that the hypochlorite is a differential germicide, that it destroys some bacteria more readily than others. When small quantities are employed certain species growing at body temperature are only slightly affected. In Pittsburgh it was found that 0.13 part of chlorinated lime, measured in terms of available chlorin per 1,000,000 parts of water, was sufficient to prac-

tically sterilize the Allegheny River water after it had passed the sand filters. It required as much as 1 part per 1,000,000 to accomplish the same results in the raw water. In Minneapolis from 2 to 4 parts per 1,000,000 have been used. In the Jersey City case, already referred to, 5 pounds of bleaching powder, containing 35 per cent. of available chlorin, are added to each million gallons of water treated. The raw water in this case is not highly polluted, ranging as low as 30 bacteria per cubic centimeter, and rarely going over 15,000. The number of bacteria in the treated water averages only 15 bacteria per cubic centimeter, and *B. coli* is practically absent. It was found only once out of 455 samples.

*Summary.*—The purification of water by means of a little bleaching powder is cheap, reliable, efficient, harmless, and easy of application, all of which make it an attractive method. When added in proper quantities it leaves no undesirable chemical substance in the water. It must, however, be remembered that bleaching powder in no sense clarifies a water. In fact, turbidity interferes with its action to a certain extent. It cannot, therefore, render a turbid supply satisfactory. Furthermore, while chlorinated lime in such small quantities will kill bacteria it will not purify organic matter nor cure discoloration, nor take away the unpleasant smells which raw waters often contain. It is, in fact, least effective when water is most polluted with organic matter. It is especially useful in a clean water; hence, turbid and polluted waters should have a preliminary process.

In spite of the enormous improvement effected in the safety of public water supplies in this country by chlorination, the danger of water-borne typhoid is by no means a thing of the past. Epidemics are occurring from time to time as a result of mismanagement, neglect and other causes.

Chlorinated lime has a slight tendency to add to the hardness, while chlorinated soda renders the water correspondingly soft. The latter, however, is more expensive than the former.

Impure waters containing organic matter of any kind may, when attacked by hypochlorites, give rise to unpleasant flavors. These substances appear related to the amins, chloramins, and other compounds the exact composition of which requires further study. Hence the chemical sterilization of impure waters without subjecting them to some preliminary treatment may give disappointing results.

Bleaching powder is also used in the disinfection of the water of swimming pools, for street sprinkling, and flushing, for the disinfection of feces and sputum; and to a certain extent, for the disinfection of glassware, fabrics, brushes, and combs. It is one of the best substances we have for the general disinfection of rough places, such as slaughter-houses, bakehouses, dairies, outhouses, cellars, and the like.

In surgery chlorinated soda is used, the action of which is entirely analogous to chlorinated lime.

The hypochlorite treatment is also suitable for water on a small scale, as for military use, camps, tourists, explorers, and others. For *tourists* and *campers* a solution may be prepared by adding one-half a teaspoonful of chlorinated lime to one pint of water. Use one teaspoonful of this to 10 gallons; 36 drops to 1 gallon; or 9 drops to 1 quart. Let stand at least 15 minutes.

Tablets of "Halazone"<sup>5</sup> and other hypochlorites have been prepared for this purpose; they are effective only when fresh, for they are not stable.

**Chlorin.**—Liquid chlorin may be used in place of chlorinated lime. It is just as efficient and acts in practically the same manner. Its first use for the disinfection of a city water supply dates from December, 1912, at Niagara Falls, and January, 1913, at Wilmington, Delaware; by the end of 1918 there were about 2,500 liquid chlorin municipal plants in the United States.

*Chlorin gas* is formed by the electrolytic decomposition of salt solutions. The moist gas evolved from the electrolytic cells is dried and then compressed into a liquid in steel cylinders of about 100 pounds capacity. The gas is controlled and measured by special apparatus and introduced into the water (or sewage) in the proper proportions to effect disinfection.

There are two general types of apparatus, one by which the chlorin gas is introduced directly into the water; this is known as *dry feed*; another by which the gas is first dissolved in a small quantity of water and the resulting chlorin solution is piped to the point of application—*wet feed*.

The gaseous chlorin process is covered by general process patents and the mechanical devices necessary for its application are likewise controlled by a few companies engaged in installing plants.

The action of chlorin gas in water is just like the action of the hypochlorites. The advantages of chlorin gas are such that it is rapidly replacing bleaching powder for the purification of many water supplies. The gas can be obtained in a pure state, the dosage can be accurately controlled, it does not deteriorate on keeping, the apparatus is compact, and the results are uniform. The cost is about the same as for bleaching powder.

The quantities added are usually expressed in parts of chlorin per million parts of water by weight; 8.3 pounds of chlorin to 1,000,000 gallons of water is the equivalent of one part per million, since a gallon of water weighs 8.3 pounds. The amounts used to disinfect the water are the same as stated under chlorinated lime, and vary in prac-

<sup>5</sup>Dakin and Dunham, *British Medical Journal*, May 26, 1917.

tice from 0.2 to 0.75 part per million, depending upon the amount of organic matter present in the water.

Good results on the typhoid rates have followed the chlorination of the water in Chicago, Baltimore, Jersey City, Milwaukee and elsewhere. Chlorination plants should always be installed in duplicate, to provide against accident or emergency. The use of a polluted water supply seems to give a communal tolerance or immunity not evidenced in cities using a pure or purified source of supply. Thus, it is often noted that typhoid and diarrheal outbreaks are especially severe and explosive in case of a breakdown or failure of the chlorinating process.

Chlorin is used to disinfect the water supply of Buffalo, New York City, Philadelphia, Chicago, Richmond, Baltimore, Detroit, Louisville, New Haven and Stamford, Conn.; New Brunswick, N. J., and very many other cities. It was also used both in the United States and abroad in many government camps, military establishments and field units during the World War.

Many state boards of health have provided traveling emergency chlorin outfits for use in epidemics. Louisiana was the first state to use a railroad coach as a laboratory for water analysis, and garage for housing machines used in collecting samples and for fighting water-borne epidemics. New Jersey uses a small automobile for both purposes, while other states merely keep hand-operated chlorin apparatus for emergency work. Uruguay, because of distances, has equipped several railroad coaches with emergency chlorin outfits.

Nearly all states have supervision not only over the design, construction and operation of water systems, but of sewage systems as well.

**Permanganate of Potash.**—Permanganate of potash was much used in India, particularly in wells during cholera epidemics; also in water tanks on board ships, and other places. Enough permanganate is added to secure a faint pink tinge, which indicates a slight excess. The permanganate acts as an oxidizing agent precisely as ozone, or similar to the hypochlorites. It is a powerful germicide, but not sufficiently so in the strength used to depend upon it. If too much is added to wells, springs, etc., so as to kill the fish, frogs, and turtles, the water may be spoiled by putrefaction of their dead bodies. Like all chemical methods, the action is not continuous; the agent expends itself in oxidizing organic matters before attacking the bacteria, and the amount necessary for the purification of a water depends, therefore, upon the amount of organic impurities in the water.

Experiments by Clark and Gage show that complete sterilization is not obtained by the use of permanganate of potash. Over 98 per cent. of the bacteria were eliminated by treating water with 0.5 part to 100,000 in from 4 to 6 hours. Larger amounts of potassium permanganate or longer time gave no better results. Potassium per-

manganate has a comparatively low efficiency with a relatively high cost, which will always limit its usefulness. Further, the method is difficult of practical application, being rather slow.

**Alum or Sulphate of Aluminium.**—The single and double sulphates of aluminium have long been used to clarify turbid waters. In the amounts used they have no direct germicidal action, nor any direct chemical action upon the water itself. The action is entirely an indirect one, and depends upon the fact that the alkaline carbonates react upon the alum to form aluminium hydrate. This salt has a large colloidal molecule and, being insoluble, is thrown out of solution as a flocculent precipitate which entangles much of the suspended matter and bacteria. In a sense the purification of water with alum corresponds very much to the clearing of coffee with the white of egg. Some of the aluminium hydrate may also combine directly with the organic matter to form undetermined compounds. The reaction is as follows:

1 grain of alum per gallon = 142 lbs. per million gallons.

1 " " " " " = 17.1 parts per million parts of water.

$$17.1 \times \frac{300}{666.7} = 7.7 \text{ parts per million of alkalinity expressed as CaCO}_3.$$

$$142:100::7.7:x = 5.5.$$

100 lbs. of alum per million gallons = 5.5 parts per million of alkalinity as  $\text{CaCO}_3$ .

In water, however, the reaction is with calcium bicarbonate:

Therefore 1 grain of alum per gallon liberates 6.8 parts per million  $\text{CO}_2$ . And 1 grain of alum per gallon converts 7.7 parts per million bicarbonate alkalinity to 7.7 parts sulphates or incrustants.

Reactions using soda ash with alum:

1 grain per gallon alum requires  $\frac{318}{666.7}$  of 17.1 = 8.2 p. p. m.

$$\text{Na}_2\text{CO}_3 = 68 \text{ lbs. per m. g. Na}_2\text{CO}_3$$

1 grain per gallon alum liberates  $\frac{132}{666.7}$  of 17.1 = 3.4 p. p. m.  $\text{CO}_2$

Since 1 grain per gallon alum = 8.2 p. p. m.  $\text{Na}_2\text{CO}_3$  and 7.7 p. p. m. of alkalinity, and 1 p. p. m. = 8.3 lbs. p. m. g., then 1 p. p. m. alkalinity as

$$\text{Na}_2\text{CO}_3 = \frac{8.2}{7.7} \times 8.3 = 8.8 \text{ lbs. per m. g.}$$

Reaction using lime with alum:

1 grain per gallon alum requires  $\frac{168}{666.7}$  of 17.1 = 4.3 p. p. m.  $\text{CaO}$  = 36 lbs. per m. g.  $\text{CaO}$ .

This liberates no  $\text{CO}_2$ .

1 grain per gallon alum with lime increases hardness 7.7 p. p. m.

It will be seen that if alum is added in just sufficient quantities to a water it leaves no undesirable constituent in the water. This is important, for there is a great prejudice against the addition of a chemical, especially alum, to drinking water. In Washington it is actually forbidden by law, despite the fact that it has been shown that in times of great turbidity the only known method of clearing the Potomac water is by the use of a coagulant such as alum. It has already been pointed out that there are many such turbid waters in our country which contain silt in such fine subdivision that even prolonged sedimentation and repeated filtration will not render them entirely clear.

In the use of alum good results depend upon adding it in just the right amount. The quantity will vary with the turbidity and the amount of calcium carbonate contained in the water. The usual amount of alum added to water is from 1 to 4 grains per gallon. This should be carefully determined from time to time, for if not enough alum is added the result is incomplete, and if too much is added it remains in the water as such. The process therefore needs constant supervision, for turbid waters usually come from turbulent streams, which are subject to sudden variations. If the process is left to automatic devices or placed in incompetent hands it is sure to give disappointing results.

Few waters may be satisfactorily purified by alum alone. Alum should be regarded as only one part of the process. Subsequent sedimentation, filtration, or hypochlorite, etc., is necessary, depending upon circumstances. Alum alone should never be depended upon to purify a sewage-polluted water. Properly combined with filtration, alum will eliminate a large percentage of the bacteria. See Mechanical Filtration, page 1122.

Most plants have been dependent upon the open market for alum. Hoover of Columbus devised in 1916 a practical method for making alum at the plant. Two parts of commercial sulphuric acid are mixed with one part of low grade bauxite ore and poured into flat boxes. In a few hours alum cake has formed in the pans, and is used without further treatment. The product has greater coagulating power, and is considerably cheaper than commercial aluminium sulphate.

**Sulphate of Iron and Lime.**—This combination is used in many places. At St. Louis it was introduced as an emergency installation to clarify the muddy waters of the Mississippi, to make a good impression during the Louisiana Purchase Exposition in 1904. It gave such satisfactory results that it was decided to continue its use.

Reaction using lime and iron (ferrous sulphate):

1 grain per gallon  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O} = 17.1 \times \frac{100}{278} = 6.2$  p. p. m. alkalinity and 100 lbs. per m. g. = 4.5 p. p. m. alkalinity.

1 grain per gallon  $\text{FeSO}_4$  converts 6.2 p. p. m. alkalinity to 6.2 p. p. m. incrustants.

To precipitate the ferrous bicarbonate first formed requires  $17.1 \times \frac{112}{278} = 6.9$  p. p. m.  $\text{CaO} = 57$  lbs. per m. g. for each grain per gallon  $\text{FeSO}_4$ .

The dissolved oxygen in the water completes the reaction, forming brown  $\text{Fe}(\text{OH})_3$ .

Lime and iron are cheaper than sulphate of aluminium. Their application is much more difficult to control adequately, and it should never be undertaken except with the assistance of a competent resident chemist and good appliances for adding the lime in any quantity that may be required by the composition of the water. At St. Louis the water is subject to the iron and lime treatment,<sup>6</sup> followed by subsidence in large basins in which the bulk of the precipitate settles. This clarified water is then chlorinated. New Orleans uses a similar method.

**Metallic Iron: the Anderson Process.**—The Anderson process (patented) for the purification of water consists in agitating the water in contact with metallic iron, a portion of which is taken into solution as ferrous carbonate. This action is brought about by the  $\text{CO}_2$  in the water which attacks the iron. Upon subsequent aëration the ferrous carbonate is oxidized and precipitated out as the insoluble ferric hydrate, which accomplishes all the good and none of the bad effects which follow the use of alum. The precipitate is partially removed by sedimentation, or filtration may complete the process. The process is used on a large scale at Antwerp, Belgium, where the water passes through long revolving cylinders containing baffle plates and loose pieces of metallic iron. As the cylinders revolve the iron is continually carried up and dropped through the water in a constant shower. The water passes slowly from one end of the cylinder to the other.

The process theoretically is an excellent one, but apparently enough iron is not always obtained in solution to accomplish the results when applied on a large scale. Especially when peaty waters are used, it seems impossible to get enough iron into solution in the time which can be allowed; or the inorganic acids may form soluble compounds with the iron, thus defeating the object of the process. Other places where the Anderson process is used are Dortrecht, Holland, Boulogne-sur-Seine, near Paris, and elsewhere.

**Copper Sulphate.**—The use of copper sulphate in drinking waters was proposed by George T. Moore of the United States Department of Agriculture in 1904. The original claim was that copper sulphate in minute amounts would poison algae which produced objectionable tastes and odors, and the further claim was made that it was also capable of

<sup>6</sup>There are 2.13 grains of iron sulphate per gallon and 7.39 grains of lime per gallon.

destroying typhoid and other pathogenic microorganisms. We know now that copper sulphate in great dilution is a specific poison for many algae and other microscopic organisms, but that it has little or no effect upon typhoid, cholera, or dysentery bacilli in the amounts used.

Copper sulphate is used in the proportion of 0.1 to 0.25 part per 1,000,000 parts of water. Some algae require larger doses. Most of the copper combines with the bodies of the microorganisms and settles with them to the bottom and in this way is removed from the water. If the water is afterwards filtered most of the remaining copper is removed. The copper remaining in the water is in such minute amounts that there seems to be no real danger in using it in this way or even in its occasional use in somewhat larger doses where the water is very bad.

The method of applying the copper is to place weighed quantities of the copper sulphate in loose cloth bags and to tow them back and forth with rowboats through the water of the reservoir until the material is dissolved. It should be remembered that, while the copper kills some species of organisms in the amounts used, it has no effect whatever upon others. Thus, Fort Worth recently found that no aëration in addition to copper sulphate was necessary to eliminate algae from the source of supply. In fact, it permits the growth of certain species by removing the retarding symbionts, thus clearing the way for stronger growths of the forms that are not directly affected. Copper sulphate may therefore entirely change the flora in a reservoir. This change is frequently accompanied by a great improvement in odors and tastes. On the other hand, the destruction or suppression of one species may be followed by an overgrowth of an equally objectionable and more hardy form. Therefore the results from the use of copper sulphate for the correction of odors and tastes in water vary from complete successes to utter failure.

It is clearly established that copper sulphate does not prevent or even materially reduce putrefaction and the tastes and odors resulting from it. According to Hazen, the method of treating water with copper sulphate is easily and quickly applied, and considerable good has come from it. The correction is only partial, however, and is not always permanent. It is not therefore to be relied upon in all cases.

### ULTRAVIOLET RAYS<sup>7</sup>

Recently the well-known germicidal power of the ultraviolet rays has been put to practical use in the sterilization of water and other substances. These rays, of short wave length, may be obtained from

<sup>7</sup> See also page 1375.

the Cooper-Hewitt mercury vapor lamp, which is very rich in ultraviolet rays.<sup>8</sup> Nagier conceived the idea that this lamp might be used for the sterilization of water, and the experiments made in France, England, and elsewhere show this assumption to be correct. As glass is opaque to ultraviolet rays, it is necessary to use quartz or lamps made of fused silica. The apparatus used in the experiments of Thresh and Bealle consists of an aluminium cylinder about 12 inches long by 6 inches in diameter containing a Cooper-Hewitt quartz lamp with an internal diaphragm, which causes the water entering at one end to travel along the cylinder in close proximity to the lamp. By an ingenious arrangement the moment the light goes out the flow of water is stopped. This small apparatus is capable of sterilizing 50 to 200 gallons of water per hour, depending upon the character of the water. In clear water many of the bacteria are killed in from 5 to 20 seconds. The resisting spores succumb in from 30 to 60 seconds, *B. coli* in from 15 to 20 seconds, *B. typhosus* from 10 to 20 seconds, cholera vibrio 10 to 15 seconds. The presence of colloidal material or turbidity retards the actions of the rays. The current used in these experiments was 6 ampères and 130 volts. The results show that a fairly clear and bright water may be practically sterilized by exposure to ultraviolet rays for a brief time. The simplicity of the apparatus and its comparative cheapness make it attractive, so that it doubtless will receive much attention in the future.

Installations may now be had for houses, hotels, swimming pools, steamships, etc.

Marseilles adopted the ultraviolet rays to purify its water supply. There are preliminary roughing filters, and the water passes the quartz tube mercury arc lamp three times. No *B. coli* were found in the treated water, and the total bacterial reduction was 98.3 per cent., and more recently a plant was installed at Henderson, Kentucky, which sterilizes water previously passed through a rapid sand filter. Good bacterial results are obtained.

The bacteria are killed by exposure to the direct action of the ultraviolet rays themselves.

The action is not influenced by temperature (0°-55° C.) and oxygen content of the water. The formation of  $H_2O_2$  is not necessary to produce sterilization. The process does not in any way clarify the water.

In 1915 there were 320 plants in the United States, comprising 20 for swimming pools. Ultraviolet rays should preferably be applied to water free of turbidity or filtered. Overdosing gives no detrimental effects other than increased cost. The water is not changed in any way chemically. Turbidity of the water or accumulation on the lamps

<sup>8</sup> Recent literature is abstracted in the U. S. Public Health Reports, December 12, 1919, p. 2821.

greatly impairs the efficiency of the rays. Direct current is now used at 110 to 500 volts. A continuous good effluent requires constant voltage and that the lamp be in good condition. The ultraviolet ray treatment of water can be made satisfactory and reliable (page 1375).

## CHAPTER VI

### WATER AND ITS RELATION TO DISEASE

Water is a vehicle for certain infections such as cholera, typhoid fever, dysentery, and other diseases, having their primary seat in the digestive tract. It may carry inorganic poisons such as lead. It is responsible for a large group of nutritional and dietetic disorders less well understood. It may contain qualities which bring about derangements of metabolism resulting in such conditions as goiter; further, it may be the medium for carrying infections now not generally regarded as water-borne, or it may lower resistance so as to favor infections not water-borne. It is also occasionally responsible for conveying animal parasites, amebae, worms, etc.

While water has an established place among the carriers of certain infections, it has not a supreme or exclusive place, and this should be kept carefully before us. The tendency to exaggerate the importance of water as a bearer of disease and death has sometimes led to overstatement. The facts are bad enough and do not require extravagant language to emphasize their importance. The greatest danger in water is pollution from human sources. All the discharges from the body: urine, feces, expectoration, secretions from the nose, and washings from the skin, find their way sooner or later into our streams, especially where modern water-carriage systems are installed for the disposal of wastes. All sewage-polluted water must be regarded as dangerous, whether there are any known cases of typhoid fever on the watershed or not. It is highly probable that the sewage of large communities always contains typhoid bacilli in larger or smaller numbers, because in large communities typhoid fever does not die out completely at any time, and carriers and missed cases are growing in interest and importance.

Water differs in several essential particulars from any other article of diet. Above all, it is partaken of raw, while perhaps 90 per cent. of all our other food is disinfected by cooking before it is used. Again, it is a vehicle which comes in contact with many objects spread over broad acres, and it is the natural vehicle for the removal of wastes from these areas. Its great solvent and erosive powers favor this action.

The relation of water supply to sickness and death has been shown with force in many cities, notably at Lowell and Lawrence, Mass.; in

Albany, N. Y.; at Jersey City and Newark, N. J.; at Philadelphia and Pittsburgh, Pa.; at Chicago, Ill.; and abroad at London, Paris, Hamburg, Altona, Berlin, and many other cities.

### THE MILLS-REINCKE PHENOMENON

Following the filtration of the water supply at Lawrence, Mass., in September, 1893, Mr. Hiram F. Mills, a member of the State Board of Health of Massachusetts, noted that a marked decrease in the general death rate of the city, and not merely in the death rate from typhoid fever, was taking place. About the same time (May, 1893) filtered Elbe River water was furnished the city of Hamburg, and Dr. J. J. Reincke, health officer of that city, in his successive annual reports, noticed that the general death rate was declining more rapidly than could possibly be accounted for by the deaths from typhoid fever alone. To this phenomenon Sedgwick and MacNutt have given the name of the "Mills-Reincke phenomenon."<sup>1</sup> In 1904 Mr. Allen Hazen, a sanitary engineer, formulated a numerical expression for the comparative effect of water purification upon typhoid fever mortality and total mortality. He said that, "where one death from typhoid fever has been avoided by the use of a better water, a certain number of deaths, probably two or three, from other causes have been avoided." Sedgwick and MacNutt examined the vital statistics of the cities of Lawrence, Mass., and Hamburg, Germany, and also of Lowell, Mass., Albany, Binghamton, and Watertown, N. Y. They found evidence of the great life-saving power of a purified water in preventing many diseases other than typhoid fever in the cities studied, except Watertown, and in this case it is possible that the purification of the public water supply has been as yet relatively imperfect. It is further to be noted that the method of purification used at Watertown is mechanical filtration.

One of the most surprising results of these studies is the disclosure of the remarkable relation existing between polluted water and infant mortality. This was emphasized especially by Dr. Reincke at Hamburg. Closely associated with infant mortality stand diarrhea and gastrointestinal disorders in relation to polluted water.

McLaughlin<sup>2</sup> has also noted the relation of a sewage-polluted water to infant mortality, and concludes that it is certain that in practically every instance, in addition to a lessened number of deaths from typhoid fever, the substitution of a safe for a polluted water supply results in

<sup>1</sup> W. T. Sedgwick and J. S. MacNutt: "The Mills-Reincke Phenomenon and Hazen's Theorem Concerning the Decrease of Mortality from Diseases Other Than Typhoid Fever Following the Purification of Public Water Supplies," *Jour. Infect. Dis.*, Vol. VII, No. 4, Aug. 24, 1910, pp. 489-564.

<sup>2</sup> *Public Health Reports*, Vol. XXVII, No. 17, April 26, 1912.

the saving of many lives from diseases which are not reported as typhoid fever. Hazen's theorem has also been studied by Arthur Lederer,<sup>3</sup> who finds a large number of affirmative statistical results.

More recent evidence from Providence, Cincinnati, Columbus, Pittsburgh, and Philadelphia does not tend to bear out the Mills-Reincke theory, except perhaps in regard to diarrheal diseases in Pittsburgh. The proposition is not demonstrated and it would be exceedingly unwise to promise a marked lowering of the general death rate as a result of the purification of water supplies alone.

## NON-SPECIFIC DISEASES DUE TO WATER

Impure water is responsible for disorders other than the specific gastro-intestinal infections, but these disorders are often obscure or overlooked. It is not always plain just what quality or what impurity in the water is responsible for these non-specific disorders, and the diseases themselves may present a vague and ill-defined clinical picture. The relationship has been worked out in only a few instances.

A turbid or malodorous water may not in itself be particularly injurious to health, but, on account of its unattractive appearance or repulsive condition, less may be taken than is necessary for the maintenance of good health. In this way water may be indirectly responsible for much harm. The drinking of too little water is a very common dietetic error.

While a polluted water may not carry specific germs, it may so undermine health or lower resistance as to favor infections not usually associated with the digestive tract, such as pneumonia and tuberculosis and the diseases responsible for infant mortality.

From the nature of the case the effects of an impure water cannot always be measured by gross results, but the cumulative or separate action of small effects often repeated may result in deranged digestion, altered metabolism, irritation of delicate membranes or sensitive organs and structures, which may lead to or hasten the course of chronic diseases.

The *organic matter* in the quantities usually contained in a natural water is not of itself harmful. This organic matter, however, does not stay in its native state, but soon putrefies, and it is suspected that some of the intermediate products of putrefaction may have toxic potency. Ordinarily these toxic substances are in minute quantities, or at least in great dilution, but under certain circumstances they may accumulate in noticeable concentration. Further, while persons habitually taking such toxic substances may soon become immune, the new-comer will not

<sup>3</sup> Arthur Lederer: *Amer. Journal Public Hygiene*, June, 1910, p. 304.

be so fortunate. The case of organic matter in water is not a clear one, and sanitarians have ever erred on the safe side in condemning waters containing much organic matter. It is well known that if the organic matter is not derived from sewage it is probably harmless. Thus, in the case of organic matter of vegetable origin, Mason has been able to find but few cases of illness traceable to peaty waters. In such instances the patients suffered from a mild and transient form of diarrhea. I am familiar with an outbreak of diarrhea traced to a dead fish caught in the water meter of a hospital. This is probably a type of water-borne disease due to organic pollution which is not infrequent. Whether in such cases the trouble is due to bacteria or to bacterial toxins, or to the degradation products of protein decomposition, cannot always be made out.

As far as the *inorganic impurities* usually found in water are concerned, the chlorids, carbonates, sulphates, and silicates, and lime, magnesia, and aluminium can scarcely be harmful in the amounts ordinarily found. It is commonly stated that water containing 500 parts per million, or 30 grains per gallon, of clay and silt is unfit for drinking purposes, on account of its irritating effects upon the gastro-intestinal tract; but beyond this probability, turbidity is of no special sanitary significance, unless the water also contains metallic poisons or objectionable chemicals.

An attempt has frequently been made to correlate the formation of concretions such as urinary and biliary calculi with the inorganic salts in water. We now know that biliary calculi usually form about a colon bacillus or a typhoid bacillus or about some pathological particle as a nucleus, and that urinary calculi probably have a similar pathogenesis. There is no known relation between these concretions in the body and the inorganic salts in water, even those in a very hard water. It is stated that a change from a soft to a hard water causes diarrhea. The relation of inorganic substances in water to goiter will be discussed separately.

## GOITER

Goiter (from guttur, throat) is a chronic enlargement of the thyroid gland, and may be due to a variety of causes.

*The functions of the thyroid gland* are due to its internal secretion, which contains iodine. The secretion of the thyroid acts as an excitant (hormone) of the metabolic rate of the body; through its action on other endocrine glands, it influences reproductive and digestive functions; and exerts some control on the functions of other organs. One of the chief functions of the thyroid is to stimulate and maintain the energy utilization of the body at a normal level, in other words to regu-

late metabolism. Hypersecretion raises the rate of metabolism of all foodstuffs, so that protein, carbohydrates and fats are consumed at an increased rate. The thyroid also exerts some control of the glycogenic content of the liver, for in hyperthyroidism the liver is not capable of the normal storing of glycogen although the body is still able to metabolize carbohydrates in usual amounts. In deficient secretion (hyposecretion) there is a diminished and retarded growth of tissues and a lowered metabolism.

The thyroid has some relationship with the sex organs,<sup>4</sup> especially in the female, the nature of which is at present but poorly understood. There often is increase of size of the thyroid at puberty or during menstruation, pregnancy and lactation. There is also some evidence that it has a detoxicating action on certain poisonous substances, but our knowledge here is meager.

There are three diseases due to disturbed function of the thyroid gland: (1) *hypothyroidism*, associated with atrophy of the gland and diminished functional activity; (2) *hyperthyroidism*, associated with enlargement of the gland and increased functional activity; (3) *simple goiter*, probably compensatory, associated with enlargement of the gland, but little or no constitutional manifestations.

*Hypothyroidism*, or *cretinism*, occurs congenitally or develops in early years of childhood, and is characterized by imperfect development of mind and body. *Myxedema* occurs mostly in women between the ages of 30 and 50 years. It is characterized by loss of expression and memory, thickening of the skin, and subsequent infiltration with a peculiar mucoid edema.

*Hyperthyroidism*, or exophthalmic goiter (also known as Graves', Basedow's or Parry's disease), is an enlargement of the thyroid gland with increased functional activity. The chief symptoms are tachycardia, exophthalmos, goiter and tremor.

### ENDEMIC OR SIMPLE GOITER

*Simple goiter* is of special interest to the sanitarian because it is frequent, widespread and readily preventable, even curable if not too far advanced. Simple goiter is a deficiency disease, due to lack of iodine in water, food, or both.

Simple goiter includes all cases of enlargement of the thyroid, except toxic goiter, exophthalmic goiter, thyroiditis, and true neoplasms of the thyroid. Simple goiter embraces types formerly called endemic, epidemic and sporadic goiter; adolescent goiter and goiter of pregnancy; also non-toxic, parenchymatous goiter, colloidal goiter, and cystic goiter. It is also called struma or bronchocele.

<sup>4</sup>In the king scorpion the thyroid is a reproductive gland.

Simple goiter is a deficiency disease characterized by a non-inflammatory enlargement of the thyroid gland, without marked functional disturbances. The goiter is a matter of concern to the patient, because (1) it is disfiguring;<sup>5</sup> (2) it may cause pressure symptoms on the trachea or surrounding structures; (3) it may be responsible for constitutional disturbances such as apathy, chilliness, constipation, asthenia and mental apprehension.

Simple goiter is rarely congenital. It usually starts at or about puberty, and the tendency diminishes after the twentieth year. Women are more susceptible than men, in the proportion of six or eight to one. This sex predisposition probably finds its explanation in the fact that the thyroid gland is associated with the physiologic processes of the female, particularly with the female generative functions. It is usually endemic, but sometimes occurs sporadically. Epidemics have been noted, but usually in endemic localities.

**Prevalence.**—The classic home of simple or endemic goiter is in the Swiss Alps. In certain regions of these mountains it is very prevalent. Thus, in Piedmont it sometimes affects more than two out of every three of the inhabitants. It also occurs in the mountains of Austria, France, and Germany, and there are a few endemic centers in Norway, Sweden, Finland, and the Baltic provinces. The traditional seat of goiter in England is in Derbyshire ("Derbyshire neck"), while Sussex and Hampshire have also been affected. There are many endemic centers in the mountains of Asia, Japan, the Asiatic Islands, Africa, Mexico, and South America. The early explorers found it among the North American Indians, as Munsen has in more recent times in the Eskimos. The region of our Great Lakes shows considerable numbers; also in sections of West Virginia, but in the United States and Canada the goiters are not large and cretinism is rare.

Marine and Kimball<sup>6</sup> in April, 1917, examined 3,872 school girls in the second decade of life, in the city of Akron, Ohio. Of this number, 2,184, or 57 per cent., were found to present simple goiter. The frequency increased with the years of age, being 41 per cent. for the years 10 to 12, inclusive, and 60 per cent. for the years 18 to 20. In West Virginia, Clarke<sup>7</sup> examined 13,836 school children of 11 counties, in 1913, and found 1,234 cases of goiter, which is 9 per cent. of the number examined. In Virginia, the same worker examined 6,432 school children in 9 counties, and found 817 cases of goiter—12 per cent. In Huntington, West Virginia, 50 per cent. of the girl students were found to be affected; in Virginia, less than 0.1 per cent. of the goiters were among boys. In Europe, an even higher incidence among school children

<sup>5</sup>The full goitrous throat is so common in some localities that it is regarded as a type of beauty. See pictures of Burne-Jones and many other artists.

<sup>6</sup>*Journ. Lab. and Clin. Med.*, 1917, III, No. 1.

<sup>7</sup>Public Health Reports, 1914, XXIX, 939.

is reported. In Bavaria, Schittenhelm and Weichardt found an incidence as high as 77 to 89 per cent. of the total school population. Hall<sup>8</sup> found 18 per cent. of 2,086 men at the University of Washington to have enlarged thyroid glands, and 31 per cent., or 1,252 women students. Smith,<sup>9</sup> an army surgeon, in 1918 examined 65,507 men between the ages of 18 and 31 at Jefferson Barracks, and established an incidence of 1.63 per cent. Kerr<sup>10</sup> found 21 per cent. of 21,182 troops at Camp Lewis, Washington, to have goiter.

The absolute number of goiter subjects in countries with high endemic index is of great social and economic importance. In France, Mayet (1900) estimates the number at 400,000. The drain on the country is better expressed by the number of cretins. In Cisleithan, Austria, there were in 1883 a total of 12,815, or 71 per 100,000; in one district in Styria a proportion of 1,045 in 100,000. In Piedmont, Lombardy, and Venetia there were in 1883, 12,882 cretins in a population of 9,565,038.

**Goiter in Animals.**—Sheep and swine, and also mules, horses and pigs have goiter, though not constantly, in endemic centers. Marine and Lenhart<sup>11</sup> also observed goiter among brook trout in fish hatcheries; rats and mice are susceptible. Marine<sup>12</sup> found that 90 per cent. of the dogs in Cleveland are affected with goiter. It is perhaps an index of our comparative concern in human and animal welfare that goiter among animals has been the object of many prophylactic measures, whereas, in the same district, the occurrence of goiter among humans has been given scanty consideration. The early days of the sheep industry in Michigan were found to be unprofitable in that a large percentage of the animals presented goiter. The abandonment of the industry was contemplated, when salt mines were opened up in the vicinity of Detroit. Heretofore, the sheep had been fed with salt obtained from a remote source. It was soon observed that the sheep fed with the local salt were better in every way; the young were born free of goiter and did not subsequently develop it. Careful investigation established the fact that the local supply of salt contained minute traces of iodine as an impurity. In Montana alone, Smith reports that about 1,000,000 pigs were lost annually on account of this disease. The condition was present at birth, the young pigs being born hairless and generally stunted. Many were dead at birth, and few survived more than 24 to 36 hours. The affected areas in some instances are sharply demarked. At times the district is confined to a creek bottom one-half mile wide. The affected

<sup>8</sup> *Northwest Medicine*, 1914, n.s., VI, 189.

<sup>9</sup> *J. A. M. A.*, 1919, LXXII, 471.

<sup>10</sup> *Arch. Int. Med.*, XXIV, No. 3, 347.

<sup>11</sup> *Johns Hopkins Hospital Bull.*, 1910, XXI, 95.

<sup>12</sup> *Arch. Int. Med.*, 1918, XXII, 41.

pigs had large thyroids with low iodine content. The addition of small quantities of iodine salts to the food eliminated the condition.

Goiter occurs among fish, seldom in the native state, but usually under conditions of artificial propagation. It has been observed that the amount of goiter in any hatchery is in proportion to the uncleanness and general lack of sanitation in the hatchery in which the fish propagate. Through the work of Marine and Lenhart, the nature of the disease was established and simple means were evolved for its reduction. In general, the measures consist of continued cleanliness of the fisheries and the supplying of food containing proper constituents, but particularly to the addition of small traces of iodine or iodine salts to the living water of the fish.

**The Cause and Prevention of Goiter.**—It is now clear that simple goiter is a deficiency disease and that it is aggravated by and increased in frequency by improper hygienic and sanitary conditions, such as overwork, overcrowding, poor ventilation, bad water supply, lack of proper personal hygiene, improper disposal of sewage, worry, and anything that makes an undue demand upon the physiologic functions of the thyroid gland contributes to the development of goiter. In accordance with this view, the prevention is clear; in fact, simple goiter is probably the easiest of all known diseases to prevent. Marine and his co-workers<sup>13</sup> used the following method with success at Akron, Ohio: Two grams sodium iodide were given in 0.2 gram doses for 10 consecutive school days, repeated each autumn and spring. This prevented the development of new goiters. The danger of iodism or exophthalmic goiter from such amounts of iodine is negligible.

The cause of goiter has long been a mystery, and certain features of the condition are still not entirely clear. It has long been associated with drinking water; in fact, remarkably good effects have been obtained in parts of Switzerland and Italy by the introduction of good drinking water. There are goiter wells in France and Switzerland, the waters of which are used successfully for the intentional production of the disease with a view to escaping compulsory military service.

The relation of water to goiter is also illustrated in Vienna. This city long boasted of the best water among all European cities. It is brought in long aqueducts and subterranean pipes from the Schneeberg, a mountain group about 6,000 feet high and 85 miles to the north of the city. This water, used since 1872, put a stop to typhoid and other gastro-intestinal diseases. The water comes from limestone formations, and has a low degree of hardness, owing to the absence of vegetation upon the catchment area. Since 1873 the number of goiters in Vienna have increased 200 per cent., and popular belief always pointed to the water as the cause. The water used by the inhabitants in many of the

<sup>13</sup> *J. A. M. A.*, Dec. 20, 1919, Vol. LXXIII, p. 1873.

goiter regions in Switzerland comes from similar limestone formations.

Further presumptive evidence that goiter is a water-borne disease is found in certain villages in the Gilgit District in India. Here eight villages adjacent to each other derive their water from a neighboring stream, and all are badly affected with goiter. Another village in the same district takes its water from a spring and has no goiter.

Another instance in which the change of water supply is said to have influenced the prevalence of goiter is that of the village of Bozel in Tarentaise. In this village, during 1848, of a population of 1,472, there were 900 cases of goiter and 109 cretins. About this time a new water supply was introduced from a source only 800 meters distant, and 16 years afterward, among practically the same population, there were only 39 cases of goiter and 58 cretins.

On the other hand, able investigators, such as Kocher, Ewald, Bircher, McCarrison<sup>14</sup> and others believe that goiter is an infection due to a living microorganism. It is in fact difficult to reconcile some of McCarrison's observations, upon the theory that the disease is simply a deficiency of iodine in the water or food. Further study may develop the fact that certain parasites may cause enlargement of the thyroid gland.

Simple goiter in this country is without doubt a deficiency disease, and may be prevented and even cured, if not too far advanced, by the use of iodine. The secondary factors which aggravate the incidence as well as the severity of the condition, such as hygiene and sanitation, must be taken into account.

## LEAD POISONING

**Lead Poisoning.**—Lead is practically never found in natural waters. The source of the lead in the water is almost always lead service pipes, or some other lead object used in collecting, storing, or delivering the water. Lead is the most dangerous inorganic substance with which our drinking water is ordinarily contaminated. Lead poisoning from this source is much more common than it is given credit for. A celebrated instance of lead poisoning occurred in Lancashire and Yorkshire, England. The water came from peaty moorlands and was delivered through lead pipes. The citizens of these towns experienced a mysterious bodily derangement for some years, until it was finally discovered that lead poisoning was prevalent. In many other places, as Somerfeld, Germany, and Lowell, Mass., numerous cases of lead poisoning due to the action of water in lead pipes have been reported.

Enormous quantities of lead service pipes are still in use, not only in the old plumbing, but in the newer installations. It is so pliable

<sup>14</sup> *Lancet*, Jan. 18 and 25, and Feb. 8, 1913.

that plumbers find it much easier to bend it around corners and angles than to make the usual connections with iron or brass pipe, and it is therefore a great temptation to put in short lengths of it in difficult places. Lead poisoning may, under certain circumstances, come from a few feet of lead pipe. The various factors that determine the corrosive action of water upon lead are very complex. It is not possible to determine by chemical tests whether or not a water has plumbisolvant action. All natural waters have some solvent power. The only sure method of determining to what degree a given water will take up lead is by testing the question experimentally under practical conditions and establishing the amount of lead taken up.

The way by which water takes up lead is first through the formation of lead oxid. This oxidation is favored by the amount of oxygen carried in the water, possibly aided by the nitrates and nitrites serving as oxygen carriers. The lead oxid may then be dissolved, more rapidly if the water is acid, or may be washed away by the currents in the state of a fine powder in suspension.

As a general rule clean (pure) waters have a greater corrosive action upon lead than turbid waters. This is partly for the reason that the mud coats the pipes and protects them mechanically. Acid waters are almost sure to take up lead if allowed to come in contact with that metal. Even so feeble an acid as carbonic acid may under certain circumstances greatly increase the plumbisolvant action of water. Soda water (highly charged with  $\text{CO}_2$  under pressure) takes up relatively large quantities, if lead pipes are used in soda water fountains or "syphon" bottles. Waters containing carbonates or sulphates are not apt to take up lead because the corresponding salts of lead are insoluble, and thus form a protecting coating. Even though a water has no plumbisolvant action, the use of lead piping, lead cooking utensils, lead-lined cisterns, etc., is entirely unjustified for domestic service, for the reason that under certain circumstances electrolytic action, changes in the character of the water, or other causes may lead to lead poisoning.

Various conditions affect the plumbisolvant action of water, such as the duration of contact, the temperature, the pressure, the season of the year, the purity of the lead, etc. Water remaining in the pipes all night naturally takes up more lead than the water that flows more or less rapidly during the day. Lead pipes were formerly used in soda water fountains and the employee who took the first drink in the morning before the proprietor arrived received a concentrated dose. Hot water has a greater solvent action than cold water; so, also, increase in pressure up to 140 pounds to the square inch. For some unexplained reason more lead is often found in the water during the winter than during the summer. The purer the lead in the pipes the freer the solvent action. New pipes give up more lead than old pipes. However,

in some cases the poisoning manifests itself only after the pipe has been in use for years. Lead pipes are purer now than formerly, owing to profitable methods of extracting the silver and other metals with which it is frequently associated. If the lead is combined with copper, zinc, or tin the lead passes into the water more quickly in consequence of galvanic action than when pure lead is used. Electrolytic action favors the solution of lead, and the modern method of grounding electric currents adds to the danger.

The various conditions of water that favor plumbisolvant action are: Those containing free acid, such as soft, peaty waters; those containing much oxygen and little dissolved salts, that is, soft waters, such as rain water; those containing organic matter, nitrites, and nitrates, that is, sewage-contaminated water in the stage of oxidization; those containing chlorids, because chlorids dissolve the protecting film of carbonates. Waters that act least upon lead are turbid waters and hard waters, especially those containing free  $\text{CO}_2$ , for here again carbonates are formed which protect the lead with an insoluble film. However, if  $\text{CO}_2$  is present in excess or under pressure the carbonates are redissolved.

It will therefore be seen that the purest, softest, and best aerated waters are especially prone to act upon lead. Distilled water will take up lead even from impure zinc pipes (containing some lead) used on board ships. Absolutely pure water probably has no appreciable action upon metals such as lead, iron, and zinc, but absolutely pure waters are not found in nature. The plumbisolvant action is in part a mechanical erosion, in part a chemical solution, and in part results from electrolytic action.

*Symptoms.*—The early symptoms of lead poisoning are sometimes vague and readily overlooked. Fatal poisoning may be caused when very little lead is taken with the water each day; the action is cumulative and the course of the intoxication is chronic; the immediate and remote effects are serious.<sup>15</sup>

The usual symptoms of chronic lead poisoning are anemia, dyspepsia, depression, constipation, colic; various forms of paralysis, especially paralysis of the extensor muscles of the forearm leading to wrist-drop; a blue line along the edges of the gums, due to the formation of sulphid of lead deposited in the tissues. Optic neuritis may come on. There is an increase in the blood pressure. Chronic lead poisoning leads to arteriosclerosis, fibrosis of the kidneys, and the remote consequences of these changes. Muscular paresis, pain and swelling of the joints, often occur and may be mistaken for "rheumatism." In some cases gout is closely simulated. The pain is usually worse at night.

The individual susceptibility to lead poisoning varies remarkably. Of a number of individuals equally exposed some will suffer and others

<sup>15</sup> For further discussion of Lead Poisoning, see page 1293.

escape. Of those who suffer, the degree of intoxication varies considerably. It is quite common to find that among the members of a family using a water containing lead only one is stricken, while the others seem to be "immune"; that is, they either do not absorb the lead or are able to eliminate it.

Mild cases of lead poisoning may show only symptoms of anemia, vague or fugitive pains, or a mild type of peripheral neuritis. This stage of lead poisoning, which does not vary essentially from other intoxications of mild degree, is readily overlooked clinically.

Lead is absorbed from the intestines and eliminated by the kidneys and the liver. It therefore may appear in either the urine or feces. Lead in the urine is always associated with albumin, and may be intermittent. That is, a well-marked case of lead poisoning may excrete urine free from both lead and albumin. However, if the feces are examined they will be found to contain lead.

*Cases.*—Lead poisoning may occur when a comparatively small surface of lead is exposed to the solvent action of the water. This is well illustrated in the following cases:<sup>16</sup>

Case 1.—A man about fifty years old contracted lead poisoning from using cistern water. Twelve feet of the service pipe was lead, and almost wholly in the water, as it was bent at right angles and ran across the cistern under the water.

Case 2.—Mrs. W., sixty-six years of age, contracted lead poisoning from a well water which was contaminated from an old lead clock weight which had been accidentally dropped into the well. The clock weight had been in the water about fourteen months before the appearance of symptoms. The well was pumped free of water and the clock weight found and removed. In two weeks from this time Mrs. W. noticed an improvement in her lameness, and in four months she was entirely well.

Case 3.—In this case the patient was poisoned by cistern water pumped through ten feet of lead pipe. The symptoms were acute multiple peripheral neuritis, with extensive paralysis. After the lead in the water was removed recovery was only partial after a period of two years.

The exact amount of lead which may be taken into the system without producing harm is not definitely known, and doubtless varies with different people, but it is known that the continuous use of water containing quantities of lead as small as 0.005 of a part per million, or about 1/33 of a grain per gallon, has caused serious injury to health.<sup>17</sup>

No instances have been recorded of ill effects upon health of persons drinking water due to copper or zinc-lined pipes.

**SPECIFIC DISEASES DUE TO WATER**

The principal diseases of man contracted by drinking infected water are typhoid fever, cholera, and dysentery. Water-borne epidemics of these diseases have frequently occurred in the history of the world. It should be remembered that endemic and sporadic cases may also contract their infections through water. The great water-borne tragedies have for a time occupied an exaggerated position. They overshadowed the less dramatic, but more insidious, and nevertheless frequent modes of transmission of infection through other channels, especially "contacts." It is only in recent years, since the water supplies of most of our large communities have been very much improved, so that water-borne epidemics have been excluded, that sanitarians have appreciated the quantitative rôle played by water as a medium of convection in distributing pathogenic microorganisms.

It is worthy of note that almost all the large water-borne outbreaks that have been investigated have been traced to a quick transfer of the infected material from the patient to the victim. Even in Pittsburgh the Typhoid Fever Commission showed that most of the fever there had been due to nearby rather than to remote pollution of the river. The greater the distance and the longer the time between the source of the infection and the use of the water, the less are the chances of harm. This we now understand as the result of several factors which have been discussed.

It is doubtful whether typhoid, cholera, or dysentery bacilli multiply in water under natural conditions, certainly to no great extent. Almost all the great water-borne epidemics of typhoid fever occur in the spring, winter, or fall of the year, when the water is very cold. Water-borne epidemics of typhoid in the summertime, when the conditions seem favorable for multiplication of the bacilli, are relatively infrequent. Assuming that in the case of typhoid there is no multiplication of the bacilli in the water, the dilution must have been enormous in many of the cases recorded; that is, there must have been very few typhoid bacilli in a tumblerful of water. If these facts are correct it illustrates how very few bacteria, when fresh and virulent, may induce disease. The experimental data from the laboratory indicate that the healthy organism may, as a rule, successfully overcome small doses of infection. Feeding experiments, especially upon the lower animals, under laboratory conditions, indicate that very large numbers of microorganisms are usually necessary to induce disease when administered by the mouth. This is only one of the many discrepancies between laboratory and natural conditions. Many large epidemics have been traced to individual instances of pollution. In the typhoid epidemics at Butler, Plym-

outh, New Haven, in Nanticoke and Reading, there were collectively 3,929 cases of typhoid fever, with 361 deaths, resulting from the careless treatment of the discharges of but one individual patient in each outbreak.

Outbreaks due to water are usually caused by the contamination of surface supplies; less often by wells and springs. It is self-evident that the great epidemics have always been caused by polluted river or lake waters, and not by ground waters. Ground water is sometimes responsible for outbreaks of typhoid fever, especially in limestone districts, as at Lausen, Switzerland; Paris, France, etc. Usually when a well becomes badly infected it is from a nearby privy or broken sewer underground, as in the instance of the Broad Street cholera epidemic in London.

Epidemics from public water supplies result from contamination by various factors. The use of a raw water into which is continually discharged the sewage of other towns has occurred at Pittsburgh, Lawrence, Niagara Falls, Albany, and Philadelphia. A city may drink the water of a lake which has become its own cesspool, as did Chicago, Cleveland, and Burlington. The pollution may come from the wastes of individual houses, as at Plymouth, or from institutions or factories; or the pollution may come from privies situated directly over the stream or on its banks, as at Ithaca; or the pollution may come indirectly after the offending matter has been deposited on the surface of the ground, later gaining access to the water course by the washing of rain or seepage through ground seams. In some instances epidemics originate through criminal thoughtlessness in a town that has been supplied with a pure or purified water. Thus a water pipe laid through a polluted pond may become sufficiently disjointed to permit admission of the infected water, as occurred at Baraboo, Wis., and Palmerton, Pa. The admission of polluted water to a pure city supply at any time is inexcusable. Epidemics have originated as a result of the unusual drain upon the water supply at times of fire, as in the case of Lawrence; or through failure of valves to operate, as in the case of Wilkinsburg, Pa.; when the ordinary water supply was judged to be insufficient and no public warning was given of the substitution as at Newburyport; or when polluted water was furnished temporarily while the filter plant was undergoing repair, as at Lawrence, Mass., in 1902, in Brewer, in Poughkeepsie, N. Y., and Millinocket, Me. Various public wells have become infected through ground seams, and have thus caused epidemics of typhoid fever at Trenton, Newport, and Mt. Savage, Md.<sup>18</sup>

In addition to the usual sources of pollution of a surface water, the following, while relatively infrequent, may be particularly dangerous,

<sup>18</sup> Harold B. Wood: "The Economic Value of Protecting the Water Supplies," *J. A. M. A.*, Oct. 2, 1909, p. 1093.

for the reason that they are apt to take place near the source of supply: discharges from water-closets of railroad trains while crossing bridges or passing the banks of reservoirs and streams; picnic parties; camping parties; construction gangs; fishermen; ferryboats and other craft upon navigable streams. The large boats plying our Great Lakes may discharge dangerous and obnoxious material very near an intake.

**Cholera**—*Cholera in London in 1854; the Case of the Broad Street Pump*.—Cholera was prevalent in London in 1854, but prevailed with epidemic intensity in the district about Broad Street. This focus was conspicuously circumscribed in area, and the disease was virulent, with great fatality. This case has become classic because it was one of the earliest instances, if not the first, in which water was proved to convey a specific disease. The circumstances were studied by Dr. John Snow and by Mr. John York, Secretary and Surveyor of the Cholera Inquiry Committee.<sup>19</sup> No less than 700 deaths occurred in St. James Parish during the seventeen weeks that the cholera raged. The death rate was 220 per 10,000 in the parish, which contained a population in 1851 of 36,406. In the adjoining districts the death rate varied from 9 to 33 per 10,000.

Dr. Snow made a careful epidemiological study of the outbreak and compiled a statistical statement of special value, which is given in its original form on the next page.

Many of the facts of this epidemic are taken from Sedgwick's excellent account in his "Principles of Sanitary Science and the Public Health," 1902, which the student is advised to read.

It will be seen that the disease broke out with special intensity upon August 30 and declined noticeably after September 10. The pump had been removed on September 8. Dr. Snow's inquiry showed that most of the victims had preferred or had access to the water of the Broad Street well, and only in a few cases was it impossible to trace any connection with that source. Thus, with regard to 73 deaths occurring in the locality of the pump and studied especially with reference to this point, it was found that there were 61 instances in which the deceased persons used to drink the water from the pump in Broad Street, either constantly or occasionally. In 6 instances no information could be obtained, and in 6 cases it was stated that the deceased persons did not drink the pump water before their illness.

On the other hand, Dr. Snow discovered that, while a workhouse (almshouse) in Poland Street was three-fourths surrounded by houses in which cholera deaths occurred, out of 535 inmates of the workhouse only 5 cholera deaths occurred. The workhouse, however, had a well of

its own in addition to the city supply, and never sent for water to the Broad Street pump. If the cholera mortality in the workhouse had been equal to that in its immediate vicinity it should have had 50 deaths.

A brewery in Broad Street employing seventy workmen was entirely exempt, but, having a well of its own, and allowances of malt liquor having been customarily made to the employees, it appeared likely that the proprietor was right in his belief that resort was never had to the Broad Street well.

It was quite otherwise in a cartridge factory at No. 38 Broad Street, where about 200 workpeople were employed, two tubs of drinking water having been kept on the premises and always filled from the Broad Street well. Among these employees eighteen died of cholera. Similar facts were elicited for other factories on the same street, all tending to show that in general those who drank the water from the Broad Street well suffered either from cholera or diarrhea, while those who did not drink that water escaped. The whole chain of evidence was made absolutely conclusive by several remarkable and striking cases in Dr. Snow's report like the following:

"A gentleman in delicate health was sent for from Brighton to see his brother at No. 6 Poland Street who was attacked with cholera and died in twelve hours, on the first of September. The gentleman arrived

after his brother's death, and did not see the body. He only stayed about twenty minutes in the house, where he took a hasty and scanty luncheon of rump steak, taking with it a small tumbler of cold brandy and water, the water being from the Broad Street pump. He went to Pentonville, and was attacked with cholera on the evening of the following day, and died the next evening.

"The deaths of Mrs. E. and her niece, who drank the water from

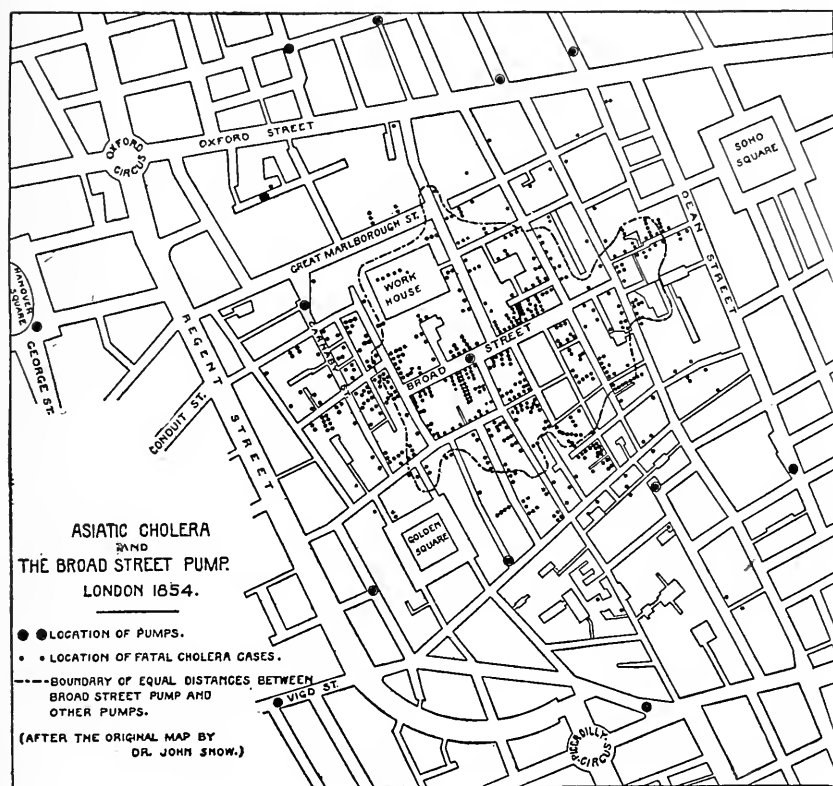

FIG. 122.

Broad Street at the West End, Hampstead, deserve especially to be noticed. I was informed by Mrs. E.'s son that his mother had not been in the neighborhood of Broad Street for many months. A cart went from Broad Street to West End every day, and it was the custom to take out a large bottle of the water from the pump in Broad Street, as she preferred it. The water was taken out on Thursday, the 31st of August, and she drank of it in the evening and also on Friday. She was seized with cholera on the evening of the latter day, and died on Saturday. A niece who was on a visit to this lady also drank of the water. She returned to her residence, a high and healthy part of

Islington, was attacked with cholera, and died also. There was no cholera at this time, either at West End or in the neighborhood where the niece died. Besides these two persons only one servant partook of the water at West End, Hampstead, and she did not suffer, or, at least, not severely. She had diarrhea."

Mr. York, Secretary and Surveyor of the Cholera Inquiry Committee, was instructed to survey the locality and examine the well, cesspool, and drains at No. 40 Broad Street.

His report revealed the following condition of affairs: The well was circular in section, 28 feet 10 inches deep, 6 feet in diameter, lined with brick, and when examined (April, 1855) contained 7 feet 6 inches of water. It was arched in at the top, dome fashion, and tightly closed at a level 3 feet 6 inches below the street by a cover occupying the crest of the dome. The bottom of the main drain of the house from No. 40 Broad Street lay 9 feet 2 inches above the water level, and one of its sides was distant from the brick lining of the well only 2 feet 8 inches. This was an old-fashioned drain 12 inches wide, with brick sides; the top and bottom were made

FIG. 123.

with old stone. It had a small fall to the main sewer. The mortar joints of the old stone bottom were found to be perished, as was also the jointing of the brick sides, which had brought the brickwork into the condition of a sieve, through which the house drainage must have percolated for a considerable period. Dr. Snow found the cesspool intended for a trap, but misconstructed, and upon and over a part of the cesspool a common privy, without water supply, for the use of the house had been erected. The brickwork of the cesspool was found to be in the same decayed condition as the drain. Dr. Snow states that, "from the charged condition of the cesspool, the defective state of its brickwork, and also that of the drain, no doubt remains upon my mind that constant percolation, and for a considerable period, had been con-

veying fluid matter from the drains into the well. A washed appearance of the ground and gravel flow corroborated this assumption. The ground between the cesspool and the well was black, saturated, and in a swampy condition, clearly demonstrating the fact." This evidence, while only circumstantial, is sufficient to connect the cesspool with the well, and can leave no doubt in the minds of those who study this interesting and instructive instance that the water became infected with cholera germs through this channel. It should be remembered that this outbreak occurred before the days of bacteriology, so that direct proof is not at hand. As far as could be determined, the infection of the well came from an unrecognized case of cholera in the house at No. 40 Broad Street. There were four severer cases of cholera subsequently in the same house.

*The Cholera Epidemic in Hamburg in 1892.*—This epidemic stands out clearly, not only as one of the most devastating of modern times, but as one of the most instructive. The relation between the infected water and the disease was conclusively proved, and the value of slow sand filtration placed upon a strong foundation. The conditions of the epidemic were equal to those of a well-controlled laboratory experiment, and the bacteriological and epidemiological evidence corroborated each other in every essential particular.

From August 17 to October 23, 1892, a little over two months, there were nearly 17,000 cases of cholera in Hamburg (population 640,000), with 8,605 deaths. On one day during the height of the epidemic over 1,000 new cases occurred. This was a pandemic year for cholera in the sense that it showed a remarkable tendency to spread to all parts of the world. It traveled from the valley of the Ganges through Persia, to Russia, Germany, Austria, France, Belgium, Holland, and the disease was brought to our own doors and several cases occurred in New York City.

Hamburg is a separate city, and at the time of the epidemic had a population of 640,000. Altona (population 143,000) is in Prussia. Politically Hamburg and Altona are separate, but geographically and actually they form one large city. The boundary runs through a street on one side of which is Hamburg, on the other Altona. Wandsbeck (population 20,000) is a nearby suburban town. Each of these three places at the time of the epidemic had a separate water supply. Wandsbeck drank filtered water from a spring little subject to pollution. Hamburg and Altona were both furnished with water from the Elbe River, which is a grossly polluted stream. Both the cities of Hamburg and Altona rest upon the bank of the Elbe River, but Altona is below or downstream. At the time of the epidemic the intake for the water supply of each city was directly at the river front, and the sewers of the city emptied into the river at various points along the same river

fronts. It will therefore be seen that Altona had Elbe River water plus Hamburg's sewage. Altona, however, first filtered this water by the slow sand process; Hamburg, however, furnished its citizens with the raw, unfiltered Elbe River water. This water was first pumped to a single reservoir, which at one time held approximately a day's supply, but had long outgrown its usefulness. It will therefore be seen that these three cities, with a homogeneous population, with the same climate,

FIG. 124.—WATER SUPPLY OF HAMBURG.

Hamburg received its water supply from the River Elbe (unfiltered) at G. The sewage of Hamburg and Altona entered the Elbe at ABC. Altona received its water supply from the Elbe at D, about 8 miles below ABC. The sand filters which purified this water were located at Blankenese. Wandsbeck had an independent water supply from a small lake.

the same low-lying site, and all other conditions similar, differed only in their water supply.

Relatively few cases occurred in Altona, and most of these were on the boundary, where the people probably had access to the raw, unfiltered Elbe River water. In Koch's own words, "cholera in Hamburg went right up to the boundary of Altona and there stopped. In one street, which for a long way forms the boundary, there was cholera on the Hamburg side, whereas the Altona side was free from it."

During the epidemic the deaths in the several cities were as follows:

	Population	Deaths	Deaths per 10,000 Inhabitants
Hamburg.....	640,400	8,605	134.4
Altona.....	143,000	328	23.0
Wandsbeck.....	20,000	43	22.0

Further evidence consisted in the fact that at one point close to and on the Hamburg side of the boundary line between Hamburg and

Altona is a large yard known as the Hamburger Platz. It contains two rows of large and lofty dwellings containing seventy-two separate tenements and some 400 people belonging almost wholly to those classes who suffer most from cholera elsewhere in Hamburg. While cholera prevailed all around no single case occurred among the many residents of this court during the whole epidemic. Koch found that, owing to local difficulties, water from the Hamburg mains could not easily be obtained for the dwellings in question, and hence a supply had been obtained from one of the Altona mains in an adjacent street. This was the only part of Hamburg that received Altona water, and it was also the only spot in Hamburg in which was aggregated a population of the class in question which escaped the cholera. The source of the epidemic was traced to Russian immigrants crowded in barracks on one of the wharves pending their embarkation for the United States, and "at the time of the outbreak there were on an average about 1,000 of these people on hand all the time. Many of them came from districts in Russia which had been, and were then, suffering severely from cholera, and all were well supplied with dirty clothing and blankets, some of which they washed while they were being detained. It is believed that among those that had arrived there must have been some mild cases of the disease, or at least some convalescents with cholera germs still in their evacuations two or three weeks after recovery. All of the sewage matters of every description from these people were discharged directly into the river at the wharf." After the Elbe River once became seeded with the cholera vibrio the people in Hamburg who drank this infected water took the disease, and their discharges, returning to the river, added fuel to the flames. A vicious circle was thus set up, so that the infection became exceedingly concentrated and intense, and as the circle was a short one the time interval was correspondingly brief and the virulence unusually severe.

The Hamburg outbreak will ever remain classic on account of the clearness of the circumstances and the fact that there is no missing link in the chain of evidence as the specific organism was readily isolated from the Elbe River water.

**Typhoid Fever**—*The Influence of Pure Water upon Typhoid Fever.*

—The effect of an improved water supply appears to have a more favorable influence upon typhoid fever than upon any other disease. The relation between water and typhoid fever has long been known, and the attention of vital statisticians has been focused upon the improvement in morbidity and mortality of this disease following the purification of a water supply. There is now reason to believe that the good effects of a pure water in preventing other diseases may possibly outweigh the good effects in typhoid alone. The typhoid figures present such clear and often dramatic proof of the value of clean water

in the conservation of health that a few of the striking tables and charts are shown upon the following pages, and should be carefully studied by the student.

For the general character of water-borne epidemics of typhoid fever and the relation of ice and cold water to typhoid see page 118.

The table on page 1170, compiled by Kober,<sup>20</sup> clearly shows the effect of improving the water supply in typhoid fever death rates in American cities:

From this table we learn that the combined average annual rate from typhoid fever in cities with a polluted supply was 69.4, and after the substitution of a purer water fell to 19.8 per 100,000—a reduction of 71.4+ per cent. The *Bulletin* of the New York State Health Department for April, 1908, shows that the death rate from typhoid fever in ten cities of that state has been reduced 53.4 per cent. by an improved water supply. Many similar instances are cited in the literature.

*Table showing the average typhoid death rate per 100,000 for a period prior to the improvement in the water supply, the average typhoid death rate per 100,000 since the change in the water supply, and the percentage of reduction caused by the improvement*

*The Typhoid Epidemic at Lausen, Switzerland.*—The epidemic of typhoid fever which occurred in Lausen, Switzerland, in 1872, was the first to attract general attention, “and, because of certain peculiar conditions connected with it, and especially because of its influence upon the theory and practice of the purification of water by filtration, it deserves the most careful consideration by all students of sanitation.” It is also interesting because of the remoteness and unusual method by which the infection reached the water supply. The following account of this epidemic is from the description by Sedgwick, quoting Dr. Hagler’s<sup>21</sup> report:

The epidemic occurred in the little village of Lausen in the canton

<sup>20</sup> “Conservation of Life and Health by Improved Water Supply,” George M. Kober, 1908.

<sup>21</sup> *Sixth Report, Rivers Pollution Commission of 1868*, London, 1874.

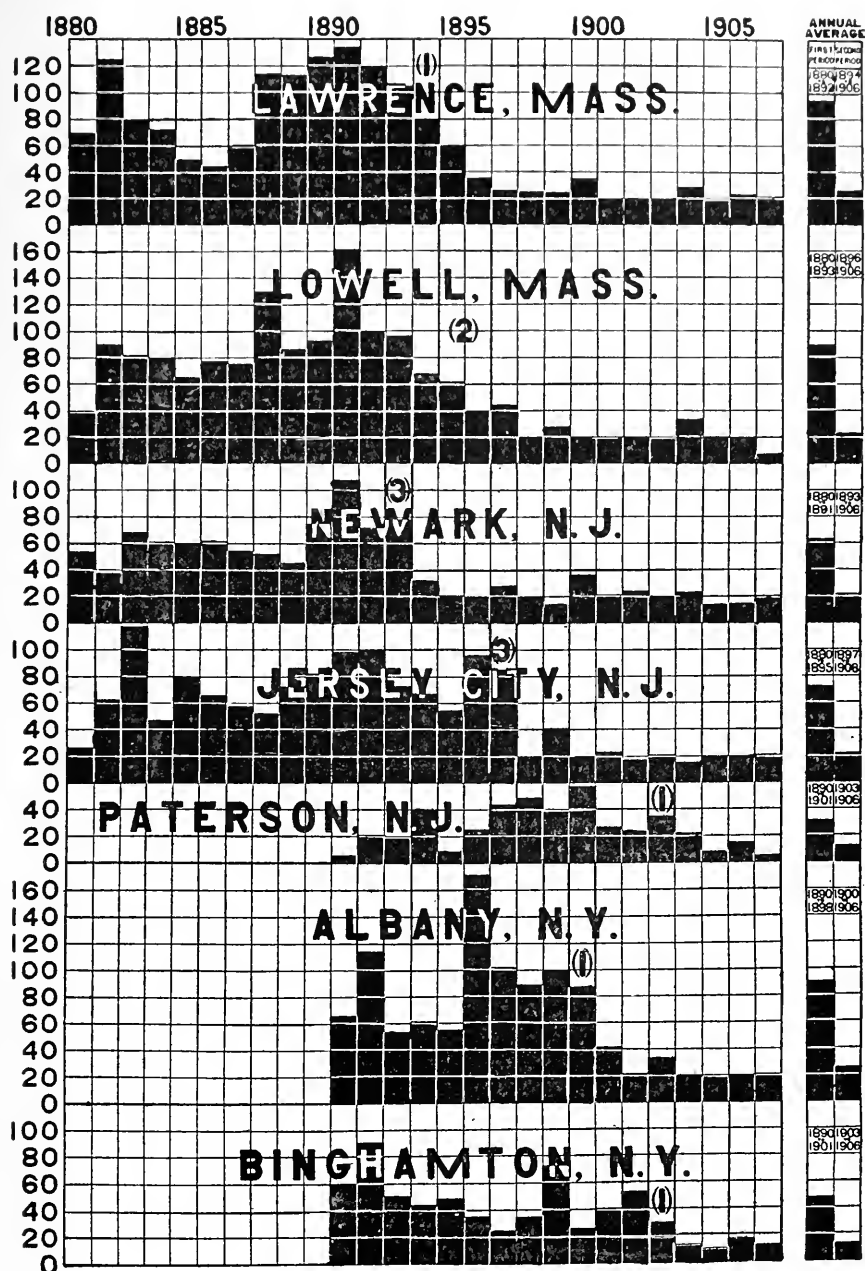

FIG. 125.—CHANGE IN WATER SUPPLY.

1. From unfiltered river supply to filtered river supply.
2. From unfiltered river supply to wells.
3. From polluted river supply to conserved river supply. (Kober.)

FIG. 126.—MEAN DEATH RATES FROM TYPHOID FEVER, 1902 TO 1906, IN 66 AMERICAN CITIES AND 7 FOREIGN CITIES GROUPED ACCORDING TO THEIR DRINKING WATER.

The rates for foreign cities are taken from James H. Fuertes. (Kober.)

of Basel in Switzerland in August, 1872. Lausen was a well-kept village of 90 houses and 780 inhabitants, and had never, so far as known, suffered from a typhoid epidemic. For many years it had not had even a single case of typhoid fever, and it had escaped cholera even when the surrounding country suffered from it. Suddenly, in August, 1872, an outbreak of typhoid fever occurred, affecting a large part of the entire population.

A short distance south of Lausen is a little valley, the Fürlethal, separated from Lausen by a hill, the Stockhalden, and in this valley, on June 19, upon an isolated farm, a peasant, who had recently been away from home, fell ill with a very severe case of typhoid fever, which he had apparently contracted during his absence. In the next two months there occurred three other cases in the neighborhood—a girl, and the wife and son of the peasant.

No one in Lausen knew anything of these cases in the remote and lonely valley, when suddenly, on August 7, 10 cases of typhoid fever appeared in Lausen, and by the end of nine days 57 cases. The number rose in the first four weeks to more than 100, and by the end of the epidemic in October to about 139, or seventeen per cent. of the population. Besides these, fourteen children who had spent their summer vacation in Lausen fell ill with the same disease in Basel. The fever was distributed quite evenly throughout the town, with the exception of certain houses which derived their water from their own wells and not from the public water supply. Attention was thus fixed upon the latter, which was obtained from a well at the foot of the Stockhalden hill on the Lausen side. The well was walled up, covered, and apparently protected, and from it the water was conducted to the village, where it was distributed by several public fountains. Only six houses used their own wells, and in these six there was not a single case of typhoid fever, while in almost all the other houses of the village, which depended upon the public water supply, cases of the disease existed. Suspicion was thus directed to the water supply as the source of the typhoid, very largely because no other source could well be imagined.

There had long been a belief that the Lausen well or spring was fed by and had a subterranean connection with a brook (the Fürler brook) in the neighboring Fürler valley; and since this brook ran near the peasant's house and was known to have been freely polluted by the excreta of the typhoid fever patients, absolute proofs of the connection between the well of Lausen and the Fürler brook could not fail to be highly suggestive and important. Fortunately, such proofs were not far to seek. Some ten years before observations had been made which had shown an intimate connection between the brook and the well. At that time, without any known reason, there had suddenly appeared near the brook in the Fürler valley below the hamlet a hole about eight

feet deep and three feet in diameter, at the bottom of which a considerable quantity of clear water was flowing. As an experiment the water of the little Fűrler brook was at that time turned into this hole, with the result that it had all flowed away underground and disappeared, and an hour or two later the public fountains at Lausen, which, on account of the dry weather prevailing at the time, were not running, had begun flowing abundantly. The water from them, which was at first turbid, later became clear; and they had continued to flow freely until the Fűrler brook was returned to its original bed and the hole had been filled up. But every year afterward, whenever the meadows below the site of the hole were irrigated, or overflowed, by the waters of the brook, the Lausen fountains soon began to flow more freely. In the epidemic year (1872) the meadows had been overflowed as usual from the middle to the end of July, which was the very time when the brook had been infected by the excrements of the typhoid patients. The water supply of Lausen had increased as usual, had been turbid at the beginning, and had had a disagreeable taste. And about three weeks before the beginning of the irrigation of the Fűrler meadows typhoid fever had broken out, suddenly and violently, in Lausen.

In order to make matters, if possible, more certain the following experiments were made, but unfortunately not until the end of August when the water of the Lausen supply had again become clear. The hole which had appeared ten years earlier, and had afterward been filled up, was reopened, and the little brook was once more led into it; three hours later the Lausen fountains were yielding double their usual volume. A quantity of brine containing about eighteen hundred pounds of common salt was now poured into the brook as it entered the hole, whereupon there appeared very soon in the Lausen water first a small, later a considerable, and finally a very strong reaction for chlorin, while the total solids increased to an amount three times as great as before the brine was added. In another experiment five thousand pounds of flour (Mehl), finely ground, were likewise added to the brook as it disappeared in the hole; but this time there was no increase of the total solids, nor were any starch grains detected in the Lausen water.

It was naturally concluded from these experiments that while the water of the brook undoubtedly passed through to Lausen and carried with it salts in solution, it nevertheless underwent a filtration which forbade the passage of suspended matters as large as starch grains. Dr. Hagler, from whose report the foregoing facts are taken, was careful, however, to state that "it is not denied that small organized particles, such as typhoid fever germs, may nevertheless have been able to find a passage." As a matter of fact Dr. Hagler's minute account does today give us some indication that such germs might easily have passed from the brook to Lausen, for the turbidity of which he repeatedly speaks is

evidence of the passage of particles as small as, and possibly smaller than, the germs of typhoid fever.<sup>22</sup>

Unfortunately this was before pure cultures of bacteria were known, and no experiments were made with suspended matters as small as bacteria. The conclusion was inevitable that although filtration had in this case sufficed to remove starch grains, it had been powerless to remove the germs of typhoid fever; and, accordingly, filtration as a safeguard against disease in drinking water fell for a time into disrepute.<sup>23</sup>

*The Typhoid Epidemic in Plymouth, Penn.*—

In 1885 the mining town of Plymouth, Penn., with a population of about 8,000, suffered with a severe outbreak of typhoid fever which involved one in every eight of the inhabitants. Plymouth received its water from a mountain brook which drained an almost uninhabited watershed. The stream was dammed at intervals and the water was stored in a series of four small impounding reservoirs. The source of the infection was traced to a citizen who spent his Christmas holidays in Philadelphia and returned home in January. He contracted typhoid; the excreta were not disinfected, but were

thrown either into the frozen creek or upon its banks within 25 or 30 feet of the edge of the stream (see map). At this time the brook was frozen and remained so until spring. There came a thaw in March and the entire accumulation was washed into the brook and thence into the water-main. Three weeks thereafter cases of typhoid by the score made their appearance throughout the town. On some days more than 100 new cases occurred.

<sup>22</sup> "Typhus und Trinkwasser," *Vierteljahresschrift für öffentliche Gesundheitspflege*, VI, 154; also *Sixth Report, Rivers Pollution Commission of 1868*, London, 1874.

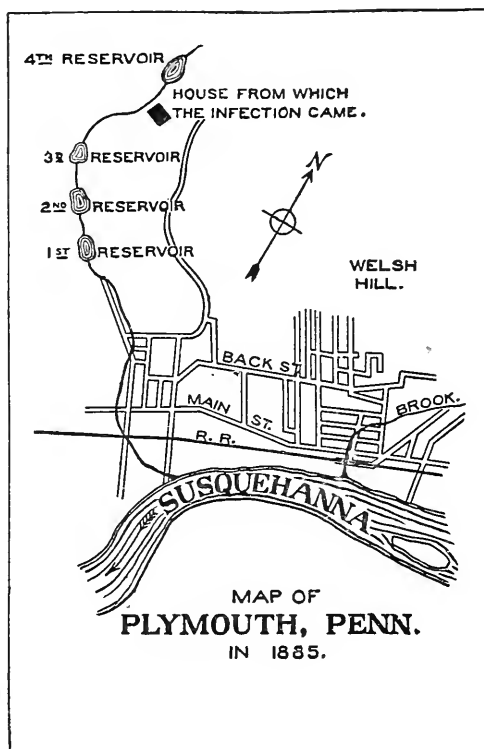

FIG. 127.

In all 1,004 cases were reported. Some estimates placed the number at 1,500, that is, 1 in every 5 of the inhabitants. There were 114 deaths. The epidemic was limited to the houses supplied with the town water or to persons who drank of the public water supply. The distinction was particularly emphasized on one street where the houses on one side had one or more cases while the houses on the other side had none at all. The former were supplied by the town water, the latter depended upon wells.

This epidemic will ever stand out in the literature as a clear-cut instance of water-borne typhoid caused by the quick transfer of virulent material from a single case. It proves further that freezing alone was not sufficient to destroy the typhoid infection, and on account of the coldness of the water it is exceedingly unlikely that any multiplication of the typhoid bacilli occurred. The infection, although greatly diluted, was nevertheless sufficiently virulent to induce the disease in most of those who drank the water. It further teaches the lesson how one person is sufficient to defile the "pure waters of a mountain brook draining an almost uninhabited territory." This epidemic was the first large outbreak in America where the cause was definitely traced to the water supply. It stands out sharply in the sanitary annals of our country on account of the lessons it taught and the good influence it had in stimulating other cities to safeguard and improve their water supplies.

*The Typhoid Epidemic at New Haven.*—Very similar to the Plymouth outbreak was that at New Haven, Conn., during April, May, and June of 1901, when 514 cases of typhoid fever occurred, resulting in 73 deaths. The outbreak was carefully studied by Professor Herbert E. Smith, who found that it was unquestionably due to an infection of one of the sources of public water supply.

The water supply in New Haven was drawn from five distinct systems. It was all surface water and was used without filtration. One of the sources was known as the Dawson supply. Dawson Lake was a storage reservoir located on West River in Woodbridge, five miles from New Haven. Dawson Lake had an area of 60 acres and a capacity of 300,000,000 gallons. There was no direct sewage pollution upon the catchment area and the rural population was only 25 per square mile.

A mile and a half above the Dawson Lake a small stream flowed into the river, and about half a mile up this stream there was a farmhouse situated at an elevation of about 180 feet above the water in the lake. Several cases occurred in this house during January and February, 1901. The excreta was thrown into a shallow privy vault without disinfection (for the reason that typhoid fever was not at first recognized). Here they accumulated and remained more or less frozen for six weeks or more. This privy was 325 feet from the brook and 40 feet above it. On March 10 and 11 there was a heavy rainfall (2.46 inches) and a

sudden thaw. The flow was so large that in spite of the intervention of the storage reservoir the water in the city was in a turbid condition on the afternoon of March 11. The typhoid fever outbreak began about 10 days later, and there seems to be little doubt that infection took place at this time. Professor Smith found that 96 per cent. of the cases that occurred were in the districts supplied with water from the Dawson Lake (Whipple).

This outbreak again illustrates the resistance of the typhoid infection to freezing, and the danger from a surface supply that for years may run satisfactorily. Even the storage reservoir failed in this case, as in the Plymouth case, to check the quick transfer of the infection. Had the Dawson supply been filtered or otherwise purified the epidemic could have been averted.

*The Typhoid Epidemic at Ashland, Wisconsin.* —

This outbreak is cited from Harrington and is one of peculiar interest, in that, in addition to serving as an excellent illustration of the danger of using

the same body of water as a place for the disposal of sewage and as a source of drinking water, it was made the basis of an action at law, which established the liability of water companies and municipalities in case of sickness and death caused by the distribution and use of infected water.

The city's supply is derived from an arm of Lake Superior, Chequamegon Bay, upon which the city is situated. This bay, which is about twelve miles long, and has an average width of five miles, varies from eight to thirty-six feet in depth. North of the city, and extending outward in a northwesterly direction, is a breakwater constructed for the protection of the harbor against northerly gales. The mouth of the water intake is located about a mile from the shore between the

FIG. 128.

breakwater and the city (see Fig. 128). The sewage of the city is discharged further to the west and south. The currents in the bay follow the course indicated by the arrows in the figure, and carry the sewage toward the breakwater and over the mouth of the intake. This condition of affairs was brought to the attention of the company by the health boards of the city and state repeatedly, but without results. That the water was polluted was evident on mere ocular inspection, for it was often cloudy or markedly turbulent. During the winter of 1893-94 typhoid fever made its appearance in the city, and from the initial cases a disastrous epidemic developed, which led to the establishment of a model filtering plant.

The action at law referred to above was brought by the widow of one of the victims. In evidence it was shown that he lived continuously in Ashland, and drank no water other than that supplied by the water company; that previous to his sickness the disease had prevailed in the city, and that the discharges from the antecedent cases had passed into the waters of the bay by way of the city sewers. The court found for the plaintiff in the sum of \$5,000.

*The Typhoid Epidemic in Mankato, Minn.*—Mankato (population 11,553) receives its water supply from four deep artesian wells on Washington Street. Two of these wells are within from 16 to 18 feet of the pumping station. The main outlet of the sewer runs down Washington Street, emptying into the river. A great flood occurred May 20 to 24, 1908. The gate in the main trunk of the sewer was let down on the night of June 24, 1908, in order to keep the river from backing up into the sewers. This caused a backing up or stasis of the sewage, which in turn backed up into a well pit of the new artesian well near the pumping station, hence sewage was pumped into the water system. Two of the other wells and suction mains were rusty and leaked and had not been properly looked after for a number of years. Then came a sudden sharp epidemic of diarrhea, June 26. Probably 2,000 persons were affected. It soon developed that the prevailing disease was typhoid fever. The epidemic lasted from June 26 and gradually died out by Nov. 20, 1908. From July 7 to Nov. 20 464 cases of typhoid fever were reported to the Health Officer. Four hundred and one of these cases were considered primary and 57 secondary or contact cases and 6 outside or imported infection.

This water-borne outbreak of typhoid fever is particularly instructive from the fact that Delia McKeever and Kate Flanagan, administratrices of the estates of their husbands, who had died of the fever, sued the city of Mankato for damages. The city demurred to this complaint on the grounds that as a government it could not be sued and was exempt because it was carrying out a government function. The Supreme Court of Minnesota held that "the state is liable if damages can be proved."

The decision of the Supreme Court in holding the city liable sets an excellent precedent which places the responsibility where it should be. Citizens are evidently as much entitled to reasonable sanitary protection as they are to police protection, or to protection from accidents at grade crossings. It is a fortunate day for preventive medicine when the principle is recognized that sanitary negligence is just as culpable as the negligence which fails to place a red flag or a red lantern to warn against a pitfall in the public highway.

*The Typhoid Epidemic in Ithaca, New York.*—In the winter of 1903 Ithaca, New York, the seat of Cornell University, was visited by a severe epidemic in the course of which 1,350 cases of typhoid fever occurred in a population of about 13,156. The population included about 3,000 students at the university. More than 500 homes were visited and there were 82 deaths. The epidemic covered a period of about 3 months and extended from about the 11th of January, 1903, to the 1st of April, although for several months before the epidemic began typhoid fever had been unduly prevalent. The epidemic was carefully studied by Dr. George A. Soper, who clearly showed that the disease was due to the public water supply, although the original case or cases which gave rise to the epidemic were not ascertained. Ithaca had at that time three separate sources of water supply. The largest one was derived from Six-Mile Creek and the second supply from Buttermilk Creek, and the third was an independent supply for the university. The conditions on the two streams were similar. Both streams were considerably polluted by the population which lived largely in villages bordering on the streams. The nearest of these villages was 5 miles above the intake. Soper found numerous other sources of contamination on the watershed, and some even in the city of Ithaca a few rods above the intake of the water-works where there were no less than 17 privies located on the precipitous banks of the creek. It was known that during the year previous to the epidemic there had been at least 6 cases of typhoid fever on the watershed. The typhoid epidemic in Ithaca followed a flood in the river.

One episode of the epidemic is worthy of special mention, namely, a secondary outbreak which resulted from the infection of a well. This well had become popular among the residents of a certain district at the time when the public supply came to be distrusted, and its good quality was taken for granted. But the wife of the owner was taken sick with typhoid fever during the epidemic, and her dejecta passed without disinfection through the water-closet, and into a drain-pipe which ran within three or four feet of the well. The joints of the drain-pipe were insecure; and the well water, which had probably been for some time grossly contaminated, finally became infected. As a result about fifty cases of

typhoid fever and five deaths were traced to people who used this well water (Whipple).

*The Typhoid Epidemic in Butler, Penn.*—Butler, Penn. (population 16,000), had an epidemic of typhoid fever in 1903. There were 1,270 cases; that is, about 8 per cent. of the population were attacked. Infection in this case was clearly water-borne and was traced to one of various points of the stream, small tributaries, or creeks. One house in particular, provided with an overhanging privy, emptied into the creek within a short distance of the pumping station.

*The Typhoid Epidemics of Lawrence and Lowell.*—During the years 1890-91 a typhoid fever epidemic occurred in Lowell and Lawrence, Mass. This epidemic illustrates with great clearness what occurs on streams which are used both as sources of water supply and as receptacles for sewage. Both cities are on the Merrimac River, which was grossly polluted by the sewage of Manchester (population 44,126), Haverhill (population 27,412), Nashua (population 19,311), Concord (population 17,004), Fitchburg (population 22,037), Newburyport (population 13,947), Marlborough (population 13,805), Clinton (population 10,424), and from other sources of pollution. In Lowell 550 cases of typhoid fever occurred from Sept., 1890, to Jan., 1891. The epidemic was carefully studied by Professor William T. Sedgwick, who made a most thorough investigation.

A short time after the epidemic in Lowell typhoid fever broke out in Lawrence, nine miles downstream, and rapidly increased. The relation between these two epidemics was most striking. Lowell discharged its sewage into the river, Lawrence drank the water without filtration. The climax of the Lawrence epidemic occurred about one month after that in Lowell. In 1892 there was a repetition of this episode. Typhoid fever in Lowell was again responsible for an increase of typhoid fever in Lawrence. As a consequence of these occurrences Lowell abandoned the river and introduced a ground water supply, while at Lawrence a filtration plant was constructed which has materially reduced the amount of typhoid fever in that city (Whipple).

*The Typhoid Epidemics of Pittsburgh and Alleghany.*—These two Pennsylvania cities are situated at the junction of the Alleghany and Monongahela Rivers, where they unite to form the Ohio. In 1900 Pittsburgh had a population of 321,616 and Alleghany 129,896. Pittsburgh takes its water from the Alleghany River at Brilliant Station, six miles above the junction of the rivers, and from the Monongahela River at a point three miles above the junction. Alleghany receives its water supply from the Alleghany River at Montrose, ten miles from the point; it is drawn from a rock-filled crib. It is practically unfiltered water. Both the Monongahela and the Alleghany Rivers are grossly polluted streams, receiving the sewage from a populous watershed; in addition

the sewers of the cities of Alleghany and Pittsburgh empty directly into these streams, and on account of the rapid growth of these cities much of this sewage entered the river dangerously near to the water intakes. The records of the Board of Health show that at this time there occurred annually upward of 5,000 cases of typhoid fever.

For about ten years centering around 1900 Pittsburgh and Alleghany had the unenviable distinction of having the highest typhoid death rate of any city in this country and probably of any large city in the world. At times the rates ran above 150 per 100,000. The conditions have recently been improved by the introduction of slow sand filtration for the city of Pittsburgh. Alleghany, which is now officially known as North Pittsburgh, was furnished (1912) with filtered water.

*The Typhoid Epidemic at Chicago.*—The Chicago epidemic is an illustration of a city using a lake water which is infected with its own sewage. The water in 1892 was taken from Lake Michigan opposite the city at several "cribs" which were 1.5 to 4 miles off-shore. The Chicago sewage was discharged all along the water-front, while the Chicago River penetrated the city with its north and south branches and, polluted almost beyond endurance, flowed out into the lake about midway between the upper and lower cribs. The pollution of the lake water was at times so intense that the foul river water could be traced to the intakes with the eye. This intolerable situation resulted in the building of the Chicago drainage canal, the object of which was to keep the sewage out of the lake and carry it down the Des Plaines and Illinois Rivers into the Mississippi. By the construction of this canal the flow of the Chicago River was reversed so that, instead of the sewage entering the lake and polluting the water supply, the water of Lake Michigan now flows westward to the Mississippi and to the Gulf of Mexico. During the years 1890, 1891, and 1892 typhoid fever was unusually prevalent in Chicago. In 1890, 1,008 of the inhabitants died from typhoid fever, in 1891 the death toll from this preventable disease was 997 and in 1892, 1,489. The present conditions in Chicago, owing to the improvements in the water supply, in the milk supply, and an attack upon the residual typhoid as contact infection, have reduced the death rate to about 2 per 100,000, which was further lowered by chlorination of the water supply.

The above water-borne typhoid fever epidemics have been selected as examples. Many more may be found in the literature. Whipple, in his book on "Typhoid Fever," cites numerous instances and gives in tabular form an impressive list of such outbreaks, with references to the literature.

**Dysentery.**—Both bacillary dysentery and amebic dysentery may be transferred through drinking water. The infection in both types of

dysentery is discharged in the feces and taken in by the mouth; there is, therefore, every opportunity for water to play the same rôle in dysentery that it plays in typhoid. However, comparatively few water-borne epidemics of bacillary dysentery have been reported; these few, nevertheless, are sufficiently conclusive to be convincing. Amebic dysentery does not occur in epidemic form, but the known facts are sufficient to incriminate water as one of the vehicles of convection.

Shiga reports outbreaks in Japan from the use of well and river water. Eldridge states that dysentery is a rural disease in Japan; the use of human feces as a fertilizer and the frequency of the infection of the numerous small streams and wells render it preëminently a water-borne disease. Whittaker<sup>24</sup> reports a water-borne epidemic of dysentery at South St. Paul, Minnesota, caused by using infected water from a fire connection. The epidemic described by Duprey which occurred at Grenada Island in 1901 is one of the best examples of a water-borne epidemic of dysentery. Shiga, in Osler's "Modern Medicine," gives the following instance:

In a village called Momma-Mura, at Nobechi, in Japan, in 1900, a dysentery epidemic broke out in houses situated near each other. It was proved that the well, used by all the households suffering from the disease, was infected with the dysentery bacillus. We have also an interesting example of river-water infection in Japan. There is a village called Mitake-Mura in the district Miyagi-Ken, through which a river flows. Fishing and swimming are prohibited in it because of fish breeding. In the late summer of 1899, the prohibition having been removed, the men of the village were very glad to be allowed to fish and swim once more in the river. However, after four or five days an epidemic of dysentery broke out with 10 patients on the first day, and increasing numbers daily afterward. There were in all 413 cases, of which 115 were boys under ten years of age. After investigation it was found that there was an epidemic of dysentery in a village higher up the river, and the water had been soiled with the infected clothes.

Epidemics of bacillary dysentery in this country in institutions have not, as a rule, been associated with water.

The *Entameba histolytica*, causing amebic dysentery, was recovered by Musgrave and Clegg<sup>25</sup> from 17 to 61 samples of the public water supply of Manila and was found in tanks used for holding distilled water and also in many wells. Recently Allan<sup>26</sup> has reported a small outbreak of amebic dysentery in North Carolina due to an infected well.

**Diarrhea.**—Polluted waters not infrequently cause diarrhea, sometimes as widespread epidemics, sometimes as small outbreaks or sporadic

<sup>24</sup> Public Health Reports, Vol. XXX, No. 48, November 26, 1915, p. 3473.

<sup>25</sup> Musgrave and Clegg: *Bull. 18*, Bu. Gov. Lab., P. I., 93; Rep. Bd. Health, P. I. 1904-05, 10.

<sup>26</sup> Allan: *J. A. M. A.*, Chicago, 1909, LIII, 1561.

cases. Whenever there is a water-borne outbreak of typhoid fever or cholera there are also a large number of cases of diarrhea and gastro-intestinal disturbances in which the precise etiological factor has not been discovered. Some of these cases may be mild instances of the major disease. Infantile diarrheas are especially prevalent at such times and very likely due to the contaminated water. Thus Reincke states that infantile diarrhea was greatly lessened after the improvement in the water supply of Hamburg. The same phenomenon was noted by Hiram O. Mills after the filtration of the water supply of Lawrence, Mass. Sedgwick noted an excessive prevalence of both typhoid fever and diarrhea in Burlington and attributed the diarrhea to the sewage contamination of the water supply. Whipple states that in Albany there was a reduction of 57 per cent. in the mortality from diarrheal diseases after the introduction of filtration in 1898. Chapin questions whether such statistical evidence is sufficient to incriminate water as an influence to the causation of diarrheal diseases.

It is generally believed that diarrhea may be brought on by changes from a hard to a soft water; also by organic and inorganic impurities.

Numerous outbreaks of diarrhea have been attributed to the following microorganisms in water, viz.: *B. coli*, *B. enteritidis* of Gaertner, *B. pyocyaneus*, *B. proteus*, *B. aërogenes capsulatus* of Welch, *B. mesentericus*, and streptococci. Water containing these and other organisms is not infrequently regarded as the cause of outbreaks of gastro-intestinal irritation. The symptoms vary greatly in intensity, but usually the disease is not fatal excepting in the young and feeble. The relation between the diarrhea and the water is usually based upon the fact that some species of microorganisms are found both in the water and in the stools. Corroborative evidence, such as the finding of specific agglutinins and other antibodies in the blood, lends countenance to the claim that the particular microorganism is, in fact, the cause of the complaint. While the evidence is not conclusive, it is suggestive, and in many cases doubtless correct.

So-called "winter cholera" is a mild diarrheal disease. It is probably water-borne, but the cause is not known. It occurs in epidemic outbreaks.

**Animal Parasites.**—The eggs, larvae, or other stages in the life cycle of various intestinal parasites may enter the body in drinking water. Thus the eggs of *Ascaris lumbricoides* discharged in the feces, which require a month for development may contaminate streams and then be returned to the mouth. Some cases of infection with this parasite probably occur in this way. *Oxyuris vermicularis*, the pinworm, and *Trichuris trichiura*, the whipworm, may similarly be contracted through drinking water. The guinea worm, *Dracunculus medinensis*, may be contracted by the mouth, in drinking water. The living embryos of

this worm are liberated and find their way into fresh water. There they enter the bodies of small fresh water crustacea, *Cyclops*, which act as intermediate hosts.

It is fairly well established that the larvae of the hookworm may be taken into the stomach through drinking water, and the same is assumed of the similar parasite of Cochin China diarrhea.

### THE SANITATION OF SWIMMING POOLS

The problem of the swimming pool is a good example of an institution devised to improve hygienic conditions, yet the device itself may be a hygienic menace. Swimming is one of the best and most exhilarating forms of exercise. It is especially suitable for the tropics. Swimming is about the only form of violent exercise that can be practiced in hot weather without danger of overheating the body. Swimming has the added hygienic advantage of promoting cleanliness.

Swimming pools are nothing more or less than common bath tubs. The growing popularity of swimming pools has led to an increased interest in the sanitary conditions that prevail in them. There is no longer any doubt that they can and sometimes do transmit disease. When the use of swimming pools is made compulsory, as is the case with pupils of some secondary schools, a serious duty of sanitary supervision and responsibility arises.

The diseases contracted in swimming pools are intestinal infections; inflammatory infections of the upper respiratory tract and conjunctiva; injury and inflammation of the ears; venereal and skin diseases, etc. Typhoid fever and diarrheal conditions have been traced on reasonably reliable evidence to swimming pools such as are installed by private individuals, or found in colleges and universities, public and private schools, gymnasiums, steamships, and special bathing establishments.

The chief danger of infection comes from the water, if not kept clean, or from the towels and swimming suits, if not disinfected. The source of the infection comes in almost all instances from the persons using the pool. One of the first essentials, therefore, in the sanitation of swimming pools is to require a shower bath with the liberal use of soap before entering the tank. At the same time, a careful examination should be made of each person to determine especially the presence of skin diseases, running ears, ulcers, conjunctivitis, venereal disease, or signs of inflammation of the upper respiratory tract.

Full showers, with soap, under inspection, should be demanded of all bathers *before* entering the pool. Especial attention should be given to the perineal region. When water strikes a person's body, the natural tendency is to urinate. This should occur in the shower, not in the pool.

Bathers should be instructed in pool sanitation. Nude bathing should be encouraged, because it favors inspection and does away with the danger of contracting infection from the swimming suit.

The water should have an initial purity equal to that of a safe drinking water and may be kept fairly clean by filtration and reasonably safe by ozone, ultraviolet rays; chlorin or bleaching powder. The combination of refiltration to clean, and ozonization to disinfect the water is the best present available method to keep the water of swimming pools in satisfactory sanitary conditions. Occasional use of sulphate of copper may be necessary to keep down excessive growth of algae.

The bathers are constantly introducing pollution and occasionally infection. To offset this, disinfection should be continuous, at least it should be most effective at the time when the pool is in use.

The disinfection of the water in the pool is economical, in that it is not necessary to change the water as often as without treatment; decency and safety require frequent changes of fresh water. Chlorin or bleaching powder are effective, but they are soon oxidized and their disinfecting power rapidly disappears. If too much chlorin or its compounds are added, the water will smart the eyes and have an unpleasant odor and taste. Copper sulphate is unreliable; ultraviolet light can be used; the best results have been obtained with ozone, for it is automatic in control, reliable in action and inexpensive in operation. One part of ozone per million parts of water will sterilize. In addition to a continuous disinfection, the water should be sterilized at least once daily. The examination of swimming pool water for colon bacilli as an index of pollution is as logical a method of control as it is in the case of drinking water.

In localities where blood-flukes, *Schistosoma*, occur, special precautions are necessary with respect to swimming pools. According to Leiper, the cercariae, which are the infective stage of the parasites and whose penetration through the skin results in infection, are unable to live in water more than 36 hours after their escape from the snails which act as intermediate hosts. Consequently, he recommends that water before it is used be stored for not less than 36 hours, better 48 hours, in reservoirs that are protected from invasion by snails.

The sanitation of swimming pools requires good construction and efficient management. The tank should be large. Roughly, at least 400 gallons of water per bather is needed. The pool should have a smooth lining. The dilution should be continuous and liberal, and the tank emptied and refilled frequently. When empty, the tank should be scraped, scrubbed, flushed, then steamed, aired and dried. The cleanliness of the tank is aided by the construction of troughs at the edges to afford place for expectoration and to prevent dirt from the floor draining into the pool. Sediment on the floor should be re-

moved with hand pumps. The filtering should be continuous and the filter of sufficient capacity to refilter all the water in the tank in eight hours. Clear water is essential not only for esthetic reasons, but to reduce the hazard of drowning.

Satisfactory hygienic conditions in swimming pools require suitable administration of the plant, including the supervision of the working force, the inspection and ablution of the bathers before they enter the water, and their instruction in pool sanitation. Finally, sterilization by boiling or steaming of the towels and bathing suits after each use will avoid one of the sources of conveying infection.

### DRINKING FOUNTAIN

The movement toward the abolition of the common drinking cup has led to the development of so-called drinking fountains, of which there are many types on the market. They may be divided into intermittent and continuous, and each in turn into those with and without suitable mouthguards.

The water should not pass through a cup of water sure to become contaminated. Experiments show that it takes a long time for *B. coli* to be eliminated from these cups. The design should be such that the user cannot touch the ball with the lips, and that waste water cannot remain so as to endanger the next user of the fountain. The Committee on Sanitary Drinking Fountains<sup>27</sup> recommended that: (1) Mouth guards are a necessity. (2) The intermittent vertical jet fountain is unqualifiedly condemned. (3) Continuous vertical jet fountains are open to suspicion. (4) A slanting jet projected with a mouthguard is perfectly safe.

### ICE

Ice was not suspected of being a vehicle by which infection could be spread until it was shown in bacteriological laboratories that typhoid and other cultures are not killed by freezing. Leidy in 1848 showed that water derived from melted ice contained not only living infusoria, but also rotifers and worms. Macfadyen proved that the temperature of liquid air ( $-315^{\circ}$  F.) does not kill bacteria. In fact, some bacteria and molds grow and multiply at temperatures as low as  $0^{\circ}$  C. See also effects of cold, page 730.

Ruata<sup>28</sup> finds even more rapid destruction. Thus, cultures of *B. coli*, four strains of another bacillus and a streptococcus were killed after four days at  $-3^{\circ}$  C. to  $-12^{\circ}$  C.

<sup>27</sup> *Journ. Am. Water Wks. Assn.*, Vol. V, 1918, 110.

<sup>28</sup> *Ann. d'Igiene*, Roma, Jan., 1918, 28, No. 1, p. 1125.

Sedgwick and Winslow <sup>29</sup> (1902) were the first to make quantitative studies on the effect of freezing upon pathogenic bacteria. They used cultures of the typhoid bacillus and showed that 50 per cent. of the organisms die at the end of the first week, 90 per cent. at the end of the second week, and practically all at the end of 12 weeks. They consider that we may be sure that in nature the destruction would exceed rather than fall short of these figures, for the experiments were made in a test-tube where all the bacteria are imprisoned, while in nature perhaps 90 per cent. are extruded during the purifying process of freezing.

As water crystallizes it excludes suspended matter and even dissolved substances. The extent to which water thus purifies itself depends, however, upon conditions, for under certain circumstances the impurities may be entangled or even concentrated during the process of freezing.

S. C. Keith <sup>30</sup> considers that low temperatures alone do not destroy bacteria. On the contrary, they appear to favor bacterial longevity, doubtless by diminishing destructive metabolism. Frozen food materials, such as ice cream, milk and egg substance, favor the existence of bacteria at low temperatures, not because they are foods, but apparently because they furnish physical conditions somewhat protective to the bacteria. It seems likely that water-bearing food materials freeze in such a way that most of the bacteria are extruded from the water crystals with other non-aqueous materials (including air) and the bacteria then lie in or among these substances without being crushed or otherwise injured. In pure water, and above all, in water in which the whole mass becomes solidly crystalline, the bacteria have no similar refuge, but are caught and ultimately mechanically destroyed between the growing crystals. This explanation would account in part for the absence of live bacteria in clear ice, their comparative abundance in "snowy" ice and "bubbly" ice, and also the fact that the more watery food materials when frozen contain the fewest, and the least watery the most living bacteria. At low temperatures metabolism ceases and the bacteria continue to exist in a state of suspended vitality similar to that exhibited by many other and higher plants which, in the far north, are subject, without apparent injury, for long periods to temperatures much below the freezing point of water.

Hilliard and Davis <sup>31</sup> state that intermittent freezing exerts a more effective germicidal action than continuous freezing. The reduction is

much less in milk and cream than in pure tap water. The degree of cold below freezing is not a very important factor in the destruction of bacteria. The bacteria are probably killed by crushing in the crystallization rather than by the cold, or by the "shock" of freezing and re-freezing.

It is necessary to distinguish between natural ice and manufactured ice.

**Natural Ice.**—Natural ice should be harvested from water of good sanitary quality and handled in a cleanly manner. Even when natural ice is obtained from a polluted water the danger is greatly reduced, not only because ice purifies itself in freezing, but because natural ice is usually stored weeks and months before it is used. There are plenty of clean, fresh streams, lakes and ponds from which an abundant supply may be obtained. It is comparatively easy to protect most ponds, from which ice is harvested, from undesirable pollution. Under natural conditions the surface layer of ice contains most of the impurities and the lower layers are relatively purer, for the reason that ice grows from above downward and extrudes both suspended and dissolved matters; the surface, however, receives additional contamination from the dust, snow, flooding and other sources. It is, therefore, good practice to plane the surface of snow ice.

The fact that natural ice is usually purer than the water from which it is taken is shown by the following analyses which give the chemical and bacterial composition of natural ice and the water from which it was frozen. In this case the water was a sewage-polluted stream:

	Ice 3 to 6 Inches Thick		Water	
Free ammonia.....	.008—	.034	.460—	.084
Albuminoid ammonia.....	.156—	.214	.146—	.276
Nitrates.....	.05 —	.20	.350—	.480
Chlorin.....	2.0 —	3.0	4.500—	6.000
Hardness.....	11.0 —	28.5	57.000—	60.000
Bacteria per c. c.....	30. —	210.	5200. —	13000.
<i>Bacillus coli</i> in.....	10 c. c.—	10 c. c.	1. —	.1
Free ammonia.....	.016—	.136	.006—	.038
Albuminoid ammonia.....	.230—	.726	.116—	.166
Nitrates.....	.0 —	.050	.260—	.400
Chlorin.....	0.8 —	3.50	5.500—	
Hardness.....	18.0 —	34.0	58.500—	62.000
Bacteria per c. c.....	2. —	60.	2500. —	3900.
<i>Bacillus coli</i> in.....	0. —	0.	1. —	0.1 c. c.

The chemical figures in this table are in parts per million.

The reduction in the number of bacteria is noteworthy. It will be noticed that there was no diminution, rather an increase in the free and albuminoid ammonia.

**Manufactured Ice.**—Manufactured ice is now universally made by the ammonia process. The condensed ammonia in expanding requires heat which it takes from surrounding objects and in this way the water is frozen. There are two distinct processes; one known as "can ice" and the other as "plate ice." In the first case the freezing takes place in rectangular cans, the water freezes from the sides of the can toward the center, and the impurities are extruded and concentrated in the core, which is often visible in a cake of can ice. In making can ice the water must first be distilled or boiled in order to drive out the air, else the resulting product will be bubbly. Plate ice is made by freezing water in large shallow tanks. The water freezes upon the surface and when of sufficient thickness is cut out and removed in blocks. In this method it is not necessary to distill or boil the water for the reason that the air is extruded naturally during the process of freezing. Plate ice should be made from water of good sanitary quality, especially as it is not usually stored a long time before it is used.

When ice is made from distilled or boiled water it should be above reproach. I have found, however, that manufactured ice may contain more bacteria than the water from which it was made. This is due to uncleanly methods. Thus six specimens of plate ice made from water containing 64 microorganisms per cubic centimeter and no colon bacilli gave the following results:

Number of Sample	Manufacturer	Organisms per Cubic Centimeter	Colon Bacillus
24	C. P. Co.....	455	Absent
29	C. P. Co.....	5,000	In 1 c. c.
26	G. Ice Co.....	230	In 10 c. c.
27	G. Ice Co.....	650	Absent
32	C.-S. Co.....	470	Absent
34	P. Ice Co.....	8	In 1 c. c.

The laborers who work "on ice," as it is termed, scrape considerable amounts of dirt from their shoes in walking over the cans and tanks, and pollution takes place from other sources.

The chemical examination of manufactured ice may show conspicuously less total solids, less chlorin and less nitrates than found in the water from which it was made. On the other hand, it may be very high in free ammonia. This is accounted for by the fact that there is always some leakage of this gas about ice factories using the ammonia process. Sometimes ammonia occurs in such quantities as to impart a distinctly alkaline taste to the manufactured ice.

There is no excuse for uncleanly methods in handling ice that is used on or in our foods. The fact that surface impurities may be washed from a cake of ice is no reason for dragging it over sputum-laden pave-

ments, over dirty railroad platforms, and similar methods familiar to all. The general use of ice is a modern innovation. It has come into vogue within the past 100 years. For the uses of ice as a preservative see page 730.

**Ice and Disease.**—A search of the literature discloses but few instances of disease attributable to impurities in ice. While the experimental evidence indicates that there is a quantitative reduction of the number of bacteria in freezing, and that the imprisoned bacteria gradually die, nevertheless experience has shown that low temperatures alone cannot be depended upon to remove the danger of typhoid infection. For example, we have the water-borne epidemic in Plymouth, Pa., in 1885, presumably produced from the frozen accumulation of typhoid excrement from a single case. Very similar to the Plymouth outbreak was that at New Haven, Conn., in 1901. In only a few isolated instances, however, has ice itself been accused of being the vehicle by which the infection of typhoid fever has been spread. It appears probable that milder intestinal diseases may be caused by highly polluted ice, of which the Rye Beach epidemic, studied by Nichols<sup>32</sup> of Boston in 1875, is a point in evidence.

Park<sup>33</sup> (1901) described an epidemic which was believed to have had its origin in ice obtained from a pond in which it was shown that the excrement from a patient sick with typhoid fever had been thrown while the pond was covered with ice.

In the second annual report of the Board of Health of Connecticut for 1882 an interesting single case of typhoid fever is cited as probably derived from ice.

Dorange<sup>34</sup> (1898) described an epidemic of typhoid fever attributed to ice among eight lieutenants in a regiment stationed at Rennes in the autumn of 1895. The implication of the ice in this instance rests upon a doubtful chain of evidence, however, and no mention is made of other possible factors.

Hutchins and Wheeler<sup>35</sup> (1903) report an epidemic of typhoid fever in the St. Lawrence State Hospital, three miles below Ogdensburg, N. Y., which seems to have been due to impure ice. The disease was endemic in the hospital for ten years, increasing from two cases with the opening of the hospital in 1890 to forty cases in 1900. Although the water supply, tested bacteriologically and chemically, gave negative results, all observers agreed that the disease was water-borne. In De-

<sup>32</sup>Nichols, A. H.: "Report on an Outbreak of Intestinal Disorder Attributable to the Contamination of Drinking Water by Means of Impure Ice," *Seventh Ann. Rep.*, S. B. H., Mass., 1876, p. 467.

cember, 1900, the source of the water supply was changed to the Oswegatchie River, a small Adirondack stream supplying Ogdensburg. This practically put a stop to the disease, for there were no cases of typhoid that were not clearly contracted elsewhere until October, 1902.

Following this eight persons were attacked, seven of whom were employees in the dining-room. It seems the milk "could not have been infected." The water was excluded and other sources studied, with negative results. The ice fell under suspicion. It had recently been taken from a newly opened ice-house. The ice had been harvested from the St. Lawrence River at about the same spot as the ice previously used. It was gathered in February and consequently had been stored for seven months. This ice disclosed a contamination of 30,400 bacteria per cubic centimeter on agar plates and 50,400 on gelatin. Of eight fermentation tubes three showed the presence of colon bacilli.

The stock of ice was then examined. In the center of certain cakes were found foreign substances in the form of black or dark brown granular matter. Examined under the microscope, this matter was found to be teeming with bacteria, from which both the colon and typhoid bacillus were isolated in pure culture.

With the discontinuance of the use of this infected ice the epidemic gradually subsided. There were in all thirty-nine cases. The evidence of this outbreak was studied by Hill, who doubted the relation of the ice to the disease.

## SECTION IX

### SEWAGE DISPOSAL

BY GEORGE C. WHIPPLE

*Professor of Sanitary Engineering in the Harvard Engineering School*

**Importance of Speedy Removal of Fecal Matter.**—The basic principle that underlies all methods of sewage disposal is to get rid of the sewage as speedily as possible, with the least nuisance to the smallest number of people, with the least damage to health or property, and at the smallest cost. Experience has shown that failure to remove human excrementitious matter promptly and properly from a community is a menace to the public health. Privies and cesspools should not be tolerated in a closely built up area. Unless more than ordinary care is exercised their existence may give opportunity for the spread of disease by insects and animals and by the pollution of local wells. Statistics show that the abandonment of privies and the substitution of sewage systems have reduced the general death rate in many a city. Thus Dr. Boobyer has reported that at Nottingham, England, in a period covering ten years typhoid fever cases occurred in 2.7 per cent. of the houses that were provided with privies, in 0.83 per cent. of the houses where pail closets were used, and in only 0.18 per cent. of the houses that had water-closets connected with the sewers. Similarly, Dr. Porter has stated that in Stockport, England, during the years 1893-7 typhoid fever occurred in 3.4 per cent. of the houses where there were privies, but in only 1.2 per cent. of the houses that had sewer connections, these figures being based on a study of over 18,000 houses. In Munich, when sewers were constructed in 1856-9 the typhoid fever death rate fell from 242 to 166 per 100,000; later, after an improved water supply and other sanitary reforms had been brought about, the typhoid fever death rate fell to a much lower figure.

By taking special precautions against the spread of infection through the agency of flies, either by preventing their breeding or preventing them from obtaining access to fecal matter, and by closing polluted wells in crowded districts, the dangers from privies and cesspools may be greatly reduced.<sup>1</sup> Sometimes it is wiser to do this in villages and small towns than to go to the expense of introducing sewage systems.

<sup>1</sup> For the dangers of polluting the soil with feces see chapter on Soil.

with perhaps the attendant difficulty and expense of purifying the sewage after collection.

Ordinarily in this country sewerage systems and public water supplies are introduced in towns where the population exceeds about 3,000, and in smaller places if the population is concentrated. This is so generally true that towns that have less than 2,500 or 3,000 population are classed as "rural," the larger towns being called "urban."

**Dry Earth System.**—The dry earth system, much in vogue before the general introduction of the water carriage system, is now but little used; yet under some conditions it has advantages. With this method the water-closets are replaced by removable water-tight receptacles, or pails, in which the fecal matter is kept covered with dry earth, ashes, or some similar material. The pails are collected at frequent intervals, preferably daily, and a clean, empty pail substituted. The material is usually buried in the ground. For isolated houses, for temporary camps of laborers, for small scattered summer colonies, and for houses situated near streams or lakes used for public water supplies this method is satisfactory, and is often the best possible method, provided that proper care is taken by the user and the collector. Cleanliness in handling, the protection of the material against flies, regular and frequent collection, occasional disinfection of the pails, and prompt burial in proper soil are essential to success.

**Water Carriage System.**—So accustomed are we to present methods of sewage that it is hard to realize that the system of water carriage of fecal matter is less than a century old. Up to 1815 the public drains of London were not permitted to receive excreta; in Boston fecal matter was rigidly excluded from the sewers until 1833; and in Paris this was the case even up to 1880.

Following the report of the Health of Towns Commission in England in 1844, water-closets were rapidly introduced, and in 1847 their connection with the sewers was required by law. The modern sewerage system, therefore, dates from about the middle of the last century. Chesbrough designed a general sewerage system in Chicago in 1855. Boston's first sewerage commission was appointed in 1875. Baltimore was without a sewerage system until within a few years, and even as late as 1912, the system was not fully completed, and many houses were not connected with it.

The introduction of the water carriage system accomplished its purpose and effectually did away with the offensive accumulations of filth around city dwellings, but it gave rise to a series of other problems that sanitarians are now endeavoring to solve. The sewers were naturally built to discharge their contents into the nearest available body of water—into river, lake, or harbor, according to the situation of the city. Where the streams were relatively large, no nuisance was caused by

doing this, but where the streams were relatively small foul conditions soon arose, and it became necessary to reduce the amount of organic matter discharged from the sewers into them. Water supplies also became infected and in some instances great epidemics followed, while infection was spread in other minor ways. Thus the problem of the removal of fecal matter was sometimes solved at one place only to reappear elsewhere. Litigation also arose between riparian owners along the water courses, involving damages caused by the pollution of the water.

The problem has thus broadened from a local one to one in which different cities and even different states have become involved. It is to the solution of these problems of maintaining our streams and lakes and harbors in a satisfactory condition that sanitarians are now earnestly devoting themselves.

**Separate and Combined Systems.**—The sewers and drains of a city are used for various purposes, the two most important ones being the removal of domestic house sewage, and the rain water that falls on roofs, yards, sidewalks, and streets. Sometimes the same system of sewers is used to carry both domestic sewage and storm water. Such is called a *combined system*. Sometimes the storm water is carried in relatively large drains, or allowed to flow along in the street gutters, while the domestic sewage is carried in a *separate system* of sewers of smaller size. The choice of the two systems depends upon the local situation, but in general the following conditions control.

The combined system is the older and the one more commonly used in large cities and crowded communities, for it is cheaper than a dual system, where both separate sewers for the house sewage and drains for the storm water are required. Where the storm water can be allowed to flow off in the gutters without serious inconvenience from flooding the separate system is cheaper, as the pipes are smaller. Where the sewage must be pumped or carried long distances in pipes or purified by expensive methods the advantages lie with the separate system, as the quantity of sewage is less and its flow more constant. From the sanitary standpoint either method is satisfactory. The choice of the two systems depends upon various engineering questions involving cost, so that the matter is one that should be submitted to an engineer.

Sewerage systems consist of *house sewers* or house drains that convey the sewage to the street sewers or *lateral sewers*. These unite in what are termed *district sewers*, and the latter sometimes unite in one or more *trunk sewers* of large size. *Relief sewers* are sometimes built parallel to old sewers of inadequate capacity, and *storm sewers* are sometimes built to carry away surface water, while *underdrains* may be used in connection with the separate system to remove some of the ground water. *Intercepting sewers* are sometimes built parallel to a stream

for collecting the sewage from a number of district sewers and conveying it to a safer point of discharge. When intercepting sewers are used with the combined system they are not designed to carry all of the flow at times of storm, but are provided with overflows, so that the excess of storm water discharges into the river at various points of overflow. This is a matter of importance and one to be remembered in connection with the purification of sewage, for the quantity of sewage that passes these overflows at times of heavy rain may amount to 25 per cent. or 50 per cent. or more of the sewage, and during the course of the year may amount to from 2 per cent. to 5 per cent., or even more, of the entire sewage of the city. Such overflow water is almost never purified. At Birmingham, England, Watson has estimated that, in spite of the elaborate provisions for purification, a large part of the city's sewage is at times discharged untreated, and at Milwaukee the Sewerage Commission estimated that nearly 2 per cent. of the sewage would fail to be collected by a very liberally designed system of intercepting sewers.

**Quantity of Sewage.**—The volume of sewage flowing in a separate system, or in a combined system during dry weather, does not differ materially from the water consumption of the city. In small towns this may be as low as 40 or 50 gallons per capita daily, although ordinarily it is rather more than this. In large cities it may amount to from 100 to 200 gallons per capita, and more than this in extreme cases.

Intercepting sewers are commonly designed to provide for a flow of 300 to 400 gallons per capita daily. The amount of storm water depends upon climatic conditions, and for this subject engineering books should be consulted. The flow of sewage fluctuates hourly, and the maximum may be from 50 to 100 per cent. of the daily average, while greater fluctuations may be found, especially in cities where large quantities of water are used in manufacturing.

**Composition of Sewage.**—A city's sewage consists of the public water supply soiled with the waste products of human life and refuse from household and factory, increased by a certain amount of ground water which leaks into the sewers, and, in the combined system, by varying quantities of rain water and street wash. Disintegrating and decomposing as it flows, the sewage gradually becomes a more or less homogeneous suspension of fine particles in water, with organic and mineral matter in solution. The longer the sewage flows or stands, the more its constituents become disintegrated; fecal matter and paper become unrecognizable as such; bacteria increase enormously, and assist in the breaking down of the complex organic compounds. The oxygen originally present in the water becomes reduced and finally disappears, so that from a fresh condition the sewage becomes first stale and then "septic." Mixed with the putrefying organic matter and the swarming hosts of bacteria harmlessly engaged in their beneficent work of de-

stroying the organic matter, there may be also bacteria which have come from persons sick with typhoid fever, dysentery, cholera, tuberculosis, and other diseases.

Sewage is obnoxious to the senses because of its decomposing organic matter, but it is dangerous to health because of the possible presence of pathogenic bacteria.

Among the important constituents of sewage from the standpoint of purification are urea, various proteid substances such as albumin, fibrin, casein; starch, sugar, and other carbohydrates, fats, soaps, and other organic substances. Important among the elements present in the easily decomposable matter are nitrogen and sulphur. The concentration of these substances, that is, the amount present in a given volume of sewage, depends upon the per capita volume of the sewage and varies widely in different places. Somewhat more constant, however, are these constituents when compared with the number of persons dwelling in houses connected with the sewers.

The following figures show the approximate constituents of sewage expressed in terms of grams per capita daily and in parts per million when the volume of sewage amounts to 100 gallons per capita daily.

## ESTIMATED CONSTITUENTS OF AVERAGE SEWAGE

(After Fuller)

		Grams per Capita Daily *	Parts per Million †
Oxygen consumed...	Two minutes boiling.....	15.0	39.6
	Five minutes boiling.....	22.0	58.0
	Free ammonia.....	7.0	18.5
Nitrogen as.....	Albuminoid ammonia.....	2.5	6.6
	Organic.....	8.0	21.1
	Total.....	15.0	39.6
Chlorin.....		19.0	50.2
Fats.....		19.0	50.2
Dissolved matter...	Total.....	136.0	359.0
	Mineral.....	99.0	261.0
	Organic and volatile.....	37.0	98.0
Suspended matters..	Total.....	66.0	246.0
	Mineral.....	58.0	140.0
	Organic and volatile.....	40.0	106.0
Total solids.....	Total.....	229.0	605.0
	Mineral.....	152.0	402.0
	Organic and volatile.....	77.0	203.0
Bacteria, 322 billion per capita daily.			

\* These figures also indicate parts per million if the per capita volume of sewage is 264 gallons per day.

† Assuming a per capita volume of 100 gallons per day.

The methods of sewage analyses at present are practically the same as those used in the analysis of water (page 1048). They are not in all respects satisfactory.

**Ventilation and Flushing of Sewers.**—The old bugaboo of sewer gas that frightened our fathers before the days of bacteriology is no longer feared by sanitarians, although its influence still pervades the antique plumbing regulations in force in many places. It is indeed desirable to keep the air of sewers from mixing with the air we breathe—the debilitating influence of all impure air should be avoided—but the danger of any one's becoming infected with the germs of disease by breathing sewer gas is negligible.

The water carriage system offers practically no danger to the public health during the transmission of sewage. In many cities the sewers are ventilated by allowing a free flow of air from the sewers through the house drains, the individual house fixtures only being trapped. This method is apparently safe, provided the plumbing is of substantial character. If it is not, it is better to place a trap upon the main house drain. It is believed that in the future plumbing will develop along the lines of simplicity and improved quality of materials and work, and that the present complicated system of traps and vents will be abandoned.

The catch-basins, through which the street wash enters the sewers, are trapped against the egress of sewer air. The water that stands in them is a prolific breeding place for mosquitoes. Unless catch-basins are frequently cleaned, the accumulating organic matter putrefies and the odor from it may be worse than that of the air of the sewer. Catch-basins are being omitted from some of the best designed modern sewerage systems.

Combined sewers are sufficiently flushed by the storms. Separate sewers, if laid on proper grades, need little or no flushing. It has been common in the past to employ flush tanks at the end of lateral sewers, but these are troublesome and waste much water.

## STREAM POLLUTION

**Sewage Disposal by Dilution.**—The readiest method of sewage disposal, and the one which, until within the last few years, has been universally practiced in this country, is to allow the sewage to flow without treatment into the nearest stream or lake or harbor. This method is known as disposal by dilution. It is a proper and satisfactory method of disposal where the dilution is sufficient. It is, however, capable of abuse, and from its abuse water supplies may become polluted, oyster beds may become infected, and in severe cases streams may be so overloaded with sewage as to become an offense to sight and smell. Properly restricted, however, the sewage is effectively disposed of, the heavy particles settle to the bottom, the organic matter is oxidized by the oxygen dissolved in the water, and the bacteria are gradually dispersed, consumed by other organisms, killed by sunlight, or otherwise destroyed.

These agencies bring about the phenomenon known as the self-purification of streams. See page 1109.

While it is true that hygienic and sanitary considerations materially affect the use of rivers and waterways as vehicles for the reception, transmission, and ultimate disposal of sewage, the question is primarily an economic one. The power of streams to transport suspended matter and the ability of natural bodies of water to oxidize and destroy offensive substances represent a natural resource that should be utilized just as far as this can be done with safety and without offense. For each river there is a limit to the amount of permissible pollution. The reasons for this limit are not the same in all cases, but vary according to the use that is made of the water of the river, and no universal standard can be wisely set up or maintained. When the extent of the pollution is such as to affect public health in any way by any reasonable use of the river the sanitary aspect of the situation should control.

The minimum amount of water required to dilute sewage in streams is usually considered to be from 2.5 to 4 cubic feet per second for the sewage of one thousand people. The Chicago Drainage Canal was designed on the basis of 3.3 cubic feet per second for one thousand people. Rapidly flowing streams require less than this, as much oxygen is absorbed from the air. Stagnant streams may require considerably more water. The presence of certain trade wastes in the sewage may materially increase the dilution required. For example, oily matters that float on the surface and form scums may interfere with the absorption of oxygen from the air.

In lakes the relation between the sewer outfall and the intake of the water works must be carefully considered, and the dispersion of bacteria by currents induced by the wind and temperature must be studied. In harbors the effects of the tides must be taken into account.

**Dissolved Oxygen in Water.**—The amount of oxygen dissolved in water depends largely upon its temperature, as shown by the figures in the table on page 1198.

Water near the freezing point will hold nearly twice as much oxygen as at prevailing summer temperatures. The dilution required in summer is therefore greater than in winter, and in some situations it would be logical to construct purification plants to be operated during the summer only, thus making a material saving in cost.

Sea water dissolves about 20 per cent. less oxygen than fresh water.

In order that the dissolved oxygen may be used to its best advantage, it is necessary to have the sewage thoroughly and quickly diffused through the water. Otherwise the oxygen near the point of discharge may be too greatly reduced, and nuisance may result, even though there be plenty of unusual oxygen near by.

*Solubility of dissolved oxygen in water—parts per million*

Temp. ° C.	Oxygen	Temp. ° C.	Oxygen	Temp. ° C.	Oxygen
0	14.70	10	11.31	20	9.19
1	14.28	11	11.05	21	9.01
2	13.88	12	10.80	22	8.84
3	13.50	13	10.57	23	8.67
4	13.14	14	10.35	24	8.51
5	12.80	15	10.14	25	8.35
6	12.47	16	9.94	26	8.19
7	12.16	17	9.75	27	8.03
8	11.86	18	9.56	28	7.88
9	11.58	19	9.37	29	7.74

**Necessity of Biological Equilibrium.**—It is becoming recognized that the problem of sewage disposal by dilution is largely a biological one. The decomposition and oxidation of the organic matter in sewage are brought about by bacteria, and the bacteria serve as food for protozoa and other forms of microscopic animal life. The dissolved organic matter in sewage serves as food for algae. These algae and protozoa are, in turn, consumed by rotifers and crustacea, while the latter form the basis of the food supply for various aquatic animals and fishes. Thus there is a continuous biological cycle. Again, animal forms require oxygen and produce carbonic acid, while plants consume carbonic acid and produce oxygen.<sup>2</sup> Where these processes occur normally and with a proper equilibrium maintained between animal and plant life, offensive conditions do not result, but where abnormal conditions are produced, as, for example, by the discharge of excessive quantities of sewage or trade wastes into a stream, a depletion of the dissolved oxygen may follow, or there may be an over-production of algae, so that the conditions become offensive. It is coming to be realized that in order properly to determine the dilution required in any particular case the conditions required to bring about this condition of biological equilibrium must be determined.

**Hygienic Aspects of Stream Pollution.**—Considering the hygienic aspects of stream pollution with special reference to the pollution of water supplies, it is important to remember that the typhoid fever bacilli do not multiply in the ordinary water of our streams, but, on the contrary, when discharged into water they rapidly diminish in number. After a week not more than 10 per cent. may remain alive, and after a month not more than 1 per cent.

It follows that recent pollution is the most dangerous, and that water stored in reservoirs and lakes becomes more and more safe for use as time of storage increases. The longevity of the typhoid bacillus is

<sup>2</sup> When fish die in sewage polluted water it is usually due to lack of oxygen.

much greater in cold water than in warm water. Hence, typhoid fever epidemics are more common in winter than in summer, and in northern climates than in southern climates.

## *PROTECTION AGAINST POLLUTION*

### WATER FILTRATION

Long experience in this country and a much longer experience in England and Germany have demonstrated clearly and unmistakably that polluted waters can be and are being constantly purified by means of filtration to such an extent that they are reliably wholesome. In Germany the typhoid fever death rates in the large cities have been reduced to figures far below those of American cities. In Europe it is not at all uncommon for the typhoid death rate to remain less than 10 per 100,000 for ten and even twenty years in succession, the rate not infrequently dropping as low as 3 and 4 per 100,000. There the filtration of surface water is required by law, and the efficiency of the filters is likewise required to rise to a certain fixed standard. It is worth remembering also that the streams of Germany are far from being unpolluted with sewage, and that no general attempt is made to provide sewage purification works of high bacterial efficiency. Only in case of actual epidemics is the practice of disinfection of sewage followed. The theory that water filtration is superior to sewage purification as a means of protecting water supplies against infection appears to prevail. The success of this policy has been amply demonstrated.

### TREATMENT OF SEWAGE

By appropriate processes sewage can be artificially purified so that the decomposable organic matter is removed or oxidized and the bacteria removed or killed. A complete purification is not attempted even in the best conducted plants, as the processes demanded are too elaborate, too expensive, and too uncertain of results. More often the purification is incomplete, the degree of purification secured being adjusted to the particular needs of the situation. In the past sewage treatment works have been built to remove as much of the decomposable organic matter as was necessary to enable the effluent to be discharged into some waterway without causing offensive conditions. This was the case in Europe, and especially in England, where the streams are relatively small and the cities relatively large and the amounts of trade waste considerable.

In some places greater emphasis has been placed on the removal or destruction of pathogenic bacteria, with the object of protecting oyster beds, bathing beaches, or reducing the "load" on water filters.

The degree of purification thus required varies all the way from a nearly complete purification down to a mere straining out of the grosser solids.

**Fundamental Principles of Sewage Treatment.**—The fundamental processes in sewage treatment are:

(1) Separation of the suspended matter from the liquid sewage.  
(2) Destruction of the putrescible organic matter in the liquid sewage looking to final mineralization by the processes of oxidation and bacterial action.

(3) The transformation of the sewage sludge to a condition of stability and inertness by bacterial action, with or without oxidation.

(4) Destruction or removal of the bacteria from the liquid effluent.

The processes involved may be classified as follows:

(1) Preparatory processes, such as screens, detritus tanks, plain settling tanks, septic tanks, digestion tanks, chemical precipitation tanks, roughing filters.

(2) Purification processes, such as sub-surface irrigation, broad irrigation, intermittent filtration, contact beds, and trickling filters.

(3) Finishing processes, such as sedimentation or coarse filtration, land treatment, disinfection.

(4) Sludge disposal by digestion tanks, filter presses, drying on land, dumping at sea.

These processes are by no means clear cut. They overlap at many points; they are used singly or in all sorts of combinations.

**Preparatory Processes—Screening.**—Sewage is screened to remove the larger substances that might injure pumps, clog filters, or appear as unsightly litter. Coarse screens consist of gratings of iron bars; fine screens of wire cloth. The amount of material screened from sewage varies from 0.1 to 1.0 cubic yard per million gallons of sewage, according to the fineness of the screens. It is pressed and burned under a boiler or buried in land. Screening has attained its greatest development in Europe.

*Fine screening* is attracting increasing attention. Screens may be called fine if the clear opening is less than about half an inch. Often the mesh is much finer than this. Naturally they clog rapidly and for that reason they are movable instead of stationary and special arrangements are made for cleaning. The collected material is usually scraped off by a continuous process from a part of the screen as it slowly emerges from the sewage. There are at least six types of fine screens: (a) The *Band Screen*, an endless flexible band of wire or links which passes over upper and lower rollers, and which is inclined in the sewage channel; (b) The *Wing Screen*, consisting of meshed vanes or paddles on a horizontal axis, and which in the lower positions, are across the path of the sewage; (c) The *Shovel-Vane Screens* which

differ from the preceding in having curved vanes; (d) The *Cylindrical Screen*, which revolves in an inclined position on an axis nearly parallel with the sewage flow, the sewage flowing through the cylinder, and the screen being kept clean by jets of water playing upon it from the outside, the screenings passing to one end of the cylinder and evacuated by means of a bucket lift; (e) The *Drum Screen*, a truncated cone of wire mesh or perforated plate, which rotates on a horizontal axis; (f) The *Inclined Disc Screen*, commonly known as the *Reinsch-Wurl Screen*, which consists of a perforated disc surmounted by a truncated cone,

FIG. 129.—INCLINED SCREEN OPERATED BY WATER WHEEL, BIRMINGHAM, ENGLAND.

which moves on an inclined axis. Of these types the last appears to be the most successful.

The openings in the plate are slots commonly about 2 m.m. wide and 30 m.m. long, staggered in rows, 6 m.m. apart, but these dimensions vary. The plate is swept by brushes as it emerges from the sewage. This process forces some of the friable solid matter through the screen, but leaves it in a finely divided state.

*Sedimentation.*—Sedimentation is the most important of the preparatory process. By allowing the sewage to flow slowly through basins in which the velocity is checked some of the suspended matter is deposited and the sewage clarified accordingly. There are five types of sedimentation basins: (1) grit chambers or detritus tanks, (2) plain settling tanks, (3) septic tanks, (4) digestion tanks, and (5) chemical precipitation tanks.

(1) *Grit Chambers.*—Grit chambers are small settling basins in which the sewage remains for a brief interval, often not more than a few minutes, and where the velocity is commonly between 10 and 30

inches per minute. They require frequent cleaning. The material collected consists largely of sand and gravel, but usually with enough organic matter to make the sludge offensive.

(2) Plain Settling Tanks.—Plain settling basins retain the sewage from one to twelve hours. The velocity of flow is commonly from 0.1

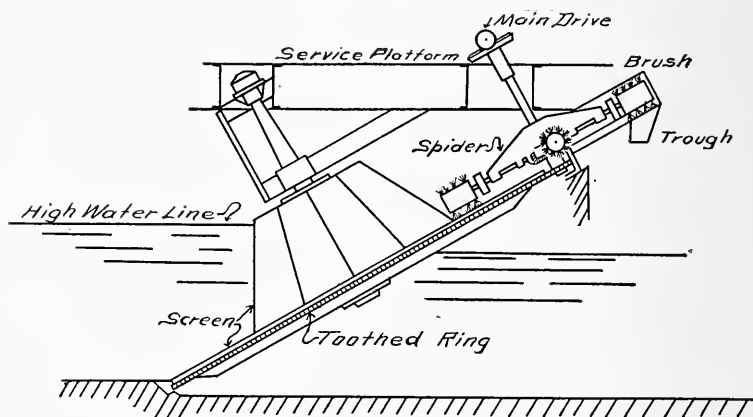

FIG. 130.—REINSCH-WURL SCREEN.

to 0.5 inch per minute. Sludge is removed at frequent intervals in order to prevent bacterial decomposition.

(3) Septic Tanks.—Septic tanks are settling tanks large enough to retain the flow of sewage from eight to twenty-four hours or longer, the velocity of flow varying from 0.1 to 0.3 inch or more per minute. The

FIG. 131.—CROSS SECTION OF SEPTIC TANK.

sludge is allowed to remain in the tanks for long periods, giving opportunity for intensified bacterial action to take place in the absence of oxygen; that is, under anaërobic conditions. As a result some of the solid organic matter is liquefied or gasified and the amount of sludge reduced. This process is spoken of as digestion. It is accompanied by the presence of a scum on the surface of the tank and a

continual rising and falling of sludge through the liquid. The amount of solid organic matter thus digested varies from 10 per cent. to 40 per cent., being greatest in strong domestic sewage. Septic action does not materially improve the quality of the effluent. It may, in fact, make it more objectionable. Septic action cannot be depended upon to render sewage safe so far as infections are concerned.

(4) Digestion Tanks. — The best known type of digestion tank is the Imhoff, or Emscher, tank. This is a deep septic tank divided by sloping partitions into an upper and a lower compartment, so arranged that the sewage flows through the upper compartment, while the sludge settles through openings in the partition walls into the lower compartment, where digestion takes place. The advantage of this type of septic tank is that the sludge alone is submitted to septic action without allowing the products of decomposition to mix with the flowing sewage above, while more complete digestion improves the character of the sludge from the standpoint of subsequent disposal.

The following figures show the approximate percentage of suspended matter removed by sedimentation:

The following figures show the approximate percentage of suspended matter removed by sedimentation:

*Percentage removal of suspended matter*

Kinds of Sedimentation	Period. Hours	Weak Sewage	Medium Sewage	Strong Sewage
Grit, or detritus tanks.....	1	10%	15%	25%
Plain sedimentation.....	6	25	40	60
Plain or septic sedimentation.....	12	30	50	75
Septic sedimentation.....	24	40	65	80
Septic sedimentation.....	48	50	75	85

FIG. 132.—TYPICAL SECTION OF AN IMHOFF TANK.

- a. Compartment for flowing sewage.
- f. Sludge digestion compartment.
- g. Baffle to prevent gases and sludge from rising into compartment a, but permitting sediment to fall into the sludge compartment.
- b-c. Pipe for withdrawing sludge.

(5) Chemical Precipitation.—Sedimentation may be hastened and increased by the use of chemicals. Lime, copperas (ferrous sulphate), and alum (aluminium sulphate) are commonly used. The active coagulants are the hydroxids of iron and aluminium. When the sewage

itself contains the necessary amount of iron, lime only is needed. When alum is used 500 to 1,500 pounds are required per million gallons. At London the sewage is treated with 500 pounds of lime and 120 pounds of copperas per million gallons; at Worcester, Mass., with 1,000 pounds of lime and no copperas; at Providence, R. I., with 600 pounds of lime and no copperas; at Glasgow with 600 pounds of lime and 1,000 pounds of copperas.

(6) Grease in Sewage.—The recovery of grease from sewage is attracting attention because of its value as a by-product and because it interferes somewhat with the biological processes of purification. In

FIG. 133.—CHEMICAL PRECIPITATION PLANT AT WORCESTER, MASS., OUTLET.

England, sulphuric acid is used to some extent, and applied to the sludge or to the raw sewage. By this means the grease is separated and removed by skimming. In this sulphurous acid, the so-called Miles Process, has been used experimentally. In the army cantonments efforts were made to eliminate grease by the use of traps of special design located on the drains from the kitchens. (Fig. 192.)

**Purification Processes—Subsurface Irrigation.**—For small installations a satisfactory method of disposing of sewage after sedimentation is to discharge it through 3-inch or 4-inch tile pipes laid in the ground 10 to 18 inches deep in rows  $2\frac{1}{2}$  to 3 feet apart. In sandy soils this method gives satisfaction, and under favorable conditions the sewage of 150 to 250 people can be applied to an acre, the rate of application being commonly one to two gallons per lineal foot, or 20,000 to 30,000 gallons per acre daily. With tight soils larger areas are required. With clay soils the method cannot be used.

This method of sewage disposal is particularly applicable to suburban and rural conditions.

*Broad Irrigation.*—Broad irrigation consists in the application of crude sewage to land, making it serve as food for crops, the principal value, however, being in the water itself. It is distributed by means of ditches and other channels as in ordinary irrigation. The sewage farms of Berlin and Paris are very extensive, the Berlin farms covering nearly 20,000 acres. The rate of application varies from 3,000 to 15,000 gallons per acre daily, an acre serving for the sewage of from 100 to 300 persons. The crops raised on sewage farms frequently pay the expenses of operation, but seldom pay the interest on the investment except in arid regions, where irrigation is profitable. Broad irrigation

FIG. 134.—TRIPLE CONTACT BEDS AT HAMPTON, ENGLAND.

cannot be successfully used with clayey soils. The purification obtained is usually very satisfactory, both chemically and bacteriologically.

*Intermittent Sand Filtration.*—With this method the sewage is applied intermittently to beds of sand, especially prepared for the purpose, in such quantities that it quickly soaks away, leaving the bed exposed to the air for a period of several hours or several days, thus giving opportunity for aëration and oxidation of the organic matter. The results obtained are usually very satisfactory, provided that the filters are not overloaded. When raw sewage is applied directly to the beds the rates of application vary from 50,000 to 150,000 gallons per acre daily, the population served per acre being from 300 to 1,200. With preliminary treatment higher rates may be used, and the sewage of 1,500 to 2,000 people applied per acre. The filters are usually divided into beds by means of earth embankments which cover the distributing pipes. Often they are underdrained with tiles laid 20 to 30 feet apart in fine material, or 100 feet apart in coarse material, their depth below the surface varying from 3 to 8 feet. Crops are sometimes grown on

these beds, but agricultural operations are regarded as a secondary matter. In winter the beds are plowed into ridges or the sludge is collected into piles so that ice may form and be supported upon them, leaving channels beneath the ice by which the sewage can be distributed. After a few weeks or months the beds become clogged and it is necessary to rake the surface. At intervals the accumulated deposit on the sand has to be scraped off.

FIG. 135.—CROSS SECTION OF INTERMITTENT SAND FILTER.

The efficiency of intermittent sand filtration is higher than that of any other process. Well operated plants are capable of removing from 95 to 98 per cent. of the suspended matter and bacteria, while the effluent is quite clear and non-putrescible. The method is limited, however, to regions where suitable and convenient areas of sandy soil exist.

*Contact Beds.*—Contact beds are water-tight compartments filled with porous material, such as broken stone or coke, and operated as follows: The bed is slowly filled with sewage, which has previously passed through a septic tank, and allowed to remain full for a brief

FIG. 136.—CROSS SECTION OF CONTACT BED.

period, after which it is emptied and allowed to remain empty for a longer period. A cycle commonly employed is to allow one hour for filling, two hours for contact, one hour for emptying, and four hours for rest. During the period of contact the suspended matter tends to settle upon and adhere to the exposed surfaces of the broken stone or coke, thus forming a film. While standing full septic action occurs and organic matter is absorbed by the film. During the resting period oxidation of this organic matter takes place. The purification obtained in this way is partial. Commonly, two or three contact beds are used in series, the effluent from the first passing to the second, and that of the

second to the third. The depth of contact beds varies from 2 to 6 or 8 feet, the broken stone or coke being from  $\frac{1}{2}$  inch to 2 inches in size. The rate of application is usually between 300,000 and 800,000 gallons per acre daily, one acre serving a population of about 5,000. When properly operated and receiving the sewage of septic tanks contact beds are capable of removing about 65 to 70 per cent. of the organic matter, 80 to 85 per cent. of bacteria, and 85 to 90 per cent. of suspended matter. Contact beds become clogged with use, and after periods varying from five to eight years it is necessary to remove the stone or coke and clean them.

*Trickling Filters.*—Trickling filters, otherwise called “sprinkling filters” or “percolating filters,” consist of beds of porous material such as broken stone, coke, or clinkers upon which the sewage is sprinkled and

FIG. 137.—TYPICAL SECTION OF A SPRINKLING FILTER.

through which it percolates to underdrains laid on a tight floor beneath. The entire bed is arranged with reference to complete aëration throughout, in order that the organic matter of the sewage may become thoroughly oxidized. The suspended matter of the sewage is not permanently retained in the beds, but is carried out in the effluent, which is turbid and requires subsequent clarification. The object of the trickling filter is to change the character of the organic matter so as to render it non-putrescible. The sewage is applied to the beds by sprinkling through fixed sprinklers or by use of traveling sprinklers, rotary or rectangular, operated by the discharging sewage or by power. The rate of application varies from 0.5 to 2.0 million gallons per acre daily, one acre of trickling filter serving a population of 10,000 or more. The beds vary in depth from 5 to 10 feet, coarser material being used for the deeper beds. Well-operated sprinkling filters receiving the effluent from plain sedimentation or septic tanks are capable of removing from 85 to 90 per cent. of the suspended matter and from 90 to 95 per cent. of bacteria, yielding an effluent that is non-putrescible. The effluent from trickling filters is not always clear, and should be passed through settling basins before discharge. This method is useful when sandy areas of sufficient size are not available for intermittent filtration or are too expensive.

*Activated Sludge Tanks.*—A recent form of tank treatment is one which combines forced aëration with bacterial action. By pumping compressed air into a tank containing sewage so that the bubbles rise through it, causing the sediment to be thoroughly agitated, the particles of suspended matter after a few weeks become coated with a bacterial slime so that colloidal particles become attached to them. When this condition has been reached sewage is allowed to pass through the tank, aëration being maintained, the result being a surprising clarification and reduction in bacterial content. A certain amount of nitrification also takes place. The operation may be conducted on the fill and draw

FIG. 138.—TRICKLING FILTER AT BIRMINGHAM, ENGLAND.

principle or on the principle of continuous flow. This process is being experimented with in many places and promising results are being obtained. In principle the process resembles that of filtration in that the colloidal substances are brought in contact with particles covered with bacterial slime, in one case the grains being scattered through the sewage, in the other the sewage being allowed to filter or percolate through the grains.

If this process proves successful on a large scale it is destined materially to alter present methods of sewage treatment, as the structures required would be very simple. The sludge is said to be relatively inoffensive and well suited to agricultural use, but it contains a large amount of water. The economy of this method will depend upon the cost of supply air and the cost of sludge disposal.

*Sludge Disposal.*—The disposal of sludge is one of the most difficult parts of sewage purification. Grit chambers collect from 0.1 to 1 cubic yard of wet sludge per million gallons of sewage; plain settling tanks from 1 to 4 cubic yards; septic tanks from 1 to 2 cubic yards.

Sludge deposited in plain settling tanks contains from 90 to 95 per cent. of water; septic tank sludge, after storage, contains from 80 to 85 per cent.; chemical precipitation sludge from 90 to 92 per cent.; Imhoff tank sludge from 80 to 90 per cent. Sludge after pressing contains from 25 to 50 per cent. of water. It has some manurial value, and is used, to some extent, on land. As a general proposition, however, the attempt to "utilize" the sludge has not met with financial success.

**Finishing Processes—Disinfection of Sewage.**—The best disinfectant for sewage or sewage effluent is "chlorid of lime," or bleaching powder, which is usually applied in the form of a 1 per cent. to 2 per

FIG. 139.—SEPTIC TANK AND CHEMICAL PRECIPITATION TANKS AT ROCHDALE, ENGLAND.

cent. solution. The quantities required are 25 to 75 pounds per million gallons for good effluents from sprinkling filters or contact beds, 75 to 125 pounds for poor effluents, 125 to 250 pounds for crude sewage, and 250 to 375 pounds for septic sewage, the time of contact required varying from about  $\frac{1}{2}$  hour to 2 or more hours. By properly applying the chemicals in these quantities it is possible to destroy from 95 to 99 per cent. of the bacteria.

**Choice of Methods.**—The choice of methods to be used in any case depends upon various considerations, such as the nature of the sewage to be treated, the allowable character of the effluent considered with reference to the use made of the water into which it is to be discharged, the availability of suitable areas of land at proper elevation, and finally the cost, both of construction and operation.

Where suitable areas of sandy soil are available the method of intermittent filtration is ordinarily the most satisfactory one that can

be adopted. This is the case in many parts of New England and in some other parts of our country. Over much of the United States, however, the soil is far too heavy to allow this method to be used satisfactorily, and when this is the case some of the newer methods must be resorted to, such as sedimentation followed by oxidation in trickling filters, contact beds, etc. Under some special conditions broad irrigation may be desirable, but, generally speaking, this method is falling into disuse. When the effluent is to be discharged into a stream used for a nearby supply of drinking water, or into the ocean or a harbor in the vicinity of oyster beds, disinfection may properly form a part of the process. Chemical precipitation is seldom used where the sewage is of a strictly domestic character, but it may be used to advantage when the sewage contains large amounts of trade wastes.

Methods for the purification of sewage are quite elastic inasmuch as the different processes may be combined in different ways. A study of the works that have been built in the United States during the last generation shows that not infrequently they have been made more elaborate than was necessary. Often a simpler design with a large capacity gives better results than an elaborate combination of processes of limited capacity. Important engineering problems are almost always involved in the laying out of sewage treatment works.

**Relative Bacterial Efficiency of Different Processes.**—By way of recapitulation the following figures are given to show the relative sanitary efficiency of various processes employed in sewage treatment:

	Percentage Removal of Bacteria
Coarse screens.....	0 to 5
Fine screens.....	10 " 20
Grit chambers.....	10 " 25
Sedimentation .....	25 " 75
Septic sedimentation.....	25 " 75
Chemical precipitation.....	40 " 80
Contact beds.....	80 " 90
Activated sludge process.....	85 " 95
Trickling filters.....	90 " 95
Intermittent sand filters.....	95 " 98
Broad irrigation.....	97 " 99
Disinfection of raw or settled sewage.....	90 " 95
Disinfection of filter effluents.....	98 " 99

These figures are mere approximations, but they serve to show how some forms of treatment, very desirable from many points of view, have a low sanitary efficiency. The septic treatment, for example, does not greatly reduce the number of bacteria in sewage; in fact, if the period of detention of the sewage in the tank is long the numbers of bacteria in the effluent may be greater than those in the raw sewage.

**Management of Sewage Treatment Works.**—Proper management of sewage treatment works is as important as proper design, and is more difficult to secure. It is a most regrettable fact that many treatment works in the United States have been badly neglected, and, in consequence, have given inefficient service. Neglect not only results in making the effluent unsatisfactory, but leaves the works themselves in an offensive condition. Neglect of small plants is more common than of plants large enough to require the entire time of one or more attendants.

Another frequent cause of failure is that treatment works are allowed to become outgrown, so that the plant becomes overloaded and the process becomes inefficient. The sewers of a city are usually designed for a long period in advance—forty or fifty years—but this is not the case with treatment works, for the reason that such works can ordinarily be enlarged when necessary. This is sound policy, for the reason that the methods of purification are constantly improving, and it is desirable to take advantage of these improvements as far as possible whenever enlargement is necessary. But, if the works are to operate satisfactorily, the enlargement must be made as the tributary population increases, taking advantage of the methods and improvement developed up to the time.

The purification of sewage is so largely a chemical and biological matter that it is desirable to have the works in charge of men trained in sanitary engineering, with a laboratory equipment at their disposal. Tests of the sewage before and after treatment should be made regularly in order to ascertain the efficiency of the process. Tests should also be made of the water into which the sewage is discharged. In the case of plants of large size, provided with laboratories, such tests are made daily, but in the case of plants too small constantly to employ a chemist tests should be made regularly by some controlling authority. Herein lies one of the functions of the State Board of Health.

**Treatment Plants as Nuisances.**—If sewage treatment works are properly designed and carefully operated, and if they are enlarged from time to time to meet the needs of the growing community, they need not be the cause of offensive conditions, but often they are, as a matter of fact, a source of nuisance in themselves. There is a natural opprobrium attached to a region where such works exist that results in a recognized deterioration of property values. The processes used for the treatment of sewage not infrequently result in odors that may be objectionable over considerable areas. Where the treatment works are entirely covered, as some kinds of works may be, little or no nuisance may result, but where, for example, the sewage is first submitted to putrefaction in a septic tank and the septic effluent then sprayed into open air upon the surface of sprinkling filters, this exposure of the atomized liquid results in the liberation of odors that may reach distances up to perhaps half a

mile from the plant, depending upon the amount and character of sewage treatment, the local topography, prevailing direction of the wind, humidity in the atmosphere, and other conditions.

Frequently high winds will carry the spray itself for several hundred feet with inevitable bacterial pollution of the air. In the operation of sprinkling filters also it has been found that at certain seasons of the year swarms of flies breed in the porous beds. These are very troublesome, if not dangerous, in the immediate vicinity of such works. In considering the need of sewage treatment it is proper to balance these possible nuisances against those resulting from the discharge of unpurified sewage into a body of water. It not infrequently happens that the installation of sewage treatment works merely substitutes one nuisance for another.

**Nuisances Caused by Trade Wastes.**—It not infrequently happens that the greatest nuisance in streams is due not so much to domestic sewage as to the presence of trade wastes that may be discharged into the stream directly, or that may be allowed to flow into the stream through the sewers. For example, the discharge of spent dye liquors may color the water of a stream for many miles; petroleum wastes from gas works may cause iridescent films to form upon the surface of the water, producing an unsightly appearance and increasing the odor directly, as well as indirectly, by excluding air from the water; the acid iron wastes from galvanizing works may cause a rusty discoloration that not only imparts a brown color to the water, but paints the rocks and submerged stumps along the shores for many miles. When nuisances of this character arise it is wise and proper to install sewage clarification plants, and sometimes more elaborate works, for such nuisances cause real damage to property and to personal comfort. Trade waste pollution may interfere with the filtration of water even more than sewage itself. Illustrations of this are the paper-mill pollutions in New York State and the acid-iron wastes in Pennsylvania.

## COÖPERATIVE SANITATION

What appears to be needed at the present time is some method of coöperation by which needed sanitary reforms can be brought about at least expense. It is unbusinesslike to compel the purification of the sewage of a large upstream city in order to protect the water supply of a small city lower down, if pure water can be furnished the latter in some better and cheaper way. Legislation that clothes the State authorities with power to prevent the pollution of streams by sewage, but does not give them power to compel the purification of water or to control pollution by trade wastes, is unfortunate. It naturally leads to litigation rather than coöperation, and may retard rather than hasten necessary

sanitary reforms. If our State authorities cannot be trusted in this matter it may be that a proper solution of the difficulty will be found in the establishment of district boards similar to those in England and Germany, such boards having jurisdiction over the limits of particular catchment areas. In some respects these natural hydrographic boundaries have advantages over artificial State boundaries. In the near future also our national government will doubtless take a hand in the matter. In whatever form the authority may be constituted the idea of coöperation should prevail, and ironclad rules against stream pollution should give way to a rational distribution of the burden of water purification and sewage treatment, and an equitable adjustment of cost made between the parties interested, thus decreasing the total expense of sanitary measures required and utilizing natural resources for the purification of sewage in water as far as this is safe.

If the system of water carriage of sewage continues in use the time will some day come when the sewage of all of our cities will be purified, partially or completely, and all surface water supplies filtered. It is proper to anticipate this consummation as far as our means permit, but meantime it is good business and sound common sense to spend our money first where it will go furthest and do the most good, building water filters and sewage treatment works, sometimes one, sometimes both, as they may be needed.

Adequate remedies against stream pollution from the standpoint of nuisance have been usually obtained by an appeal to the principles of common law. Cases involving bacterial pollution by sewage have been thus far too few to establish definite precedents. It will be interesting to see whether, in view of our increasing population, and especially the increasing growth of our cities, the courts will ultimately decide that the use of unfiltered river water as a source of water supply by riparian owners is a reasonable use of the water.

## THE RURAL PROBLEM OF SEWAGE DISPOSAL

One of the most difficult problems of modern sanitation is to secure proper disposal of fecal matter in rural communities, at summer hotels, at temporary camps of laborers, at summer colonies at beach and mountain, and at individual houses in villages and on the farm. It is difficult because the necessary structures are so small and simple that they have been thoughtlessly constructed, because adequate care of the processes is more or less disagreeable and therefore neglected, but chiefly because the inherent dangers have not been understood or appreciated.

One of the most needed reforms, and one that is happily making progress, is that of the protected privy, that is, one where the fecal

matter is received in a tight vault so constructed that the contents cannot be reached by flies, insects, rats, hens, or pigs, yet so ventilated as to prevent disagreeable odors and give opportunity for evaporation of liquids. This necessitates the liberal use of screens around the vault and on the windows and doors, and the use of a self-closing cover for the seat. The privy vault may be constructed of concrete, with bottom and walls 3 inches to 6 inches in thickness, or the vault may be replaced with a tight, removable receptacle of metal or wood placed in a screened compartment. Properly constructed privies of this character may be located near dwellings, the only conditions being those controlling offensive odors, but this presupposes greater care than is ordi-

FIG. 140.—INTERMITTENT SAND FILTRATION BED AT BROCKTON, MASS.

narily given to such matters. Preferably, therefore, they should be located at some reasonable distance from dwellings.

Privies that are not provided with water-tight vaults, but are so arranged that the fecal matter falls upon the soil, may be safe, so far as water pollution is concerned, if the soil is of proper character and if the privy is sufficiently removed from the house well; but are undesirable for other reasons. No arbitrary rules as to the necessary minimum distance of a privy from a well can be laid down, as everything depends upon the character of the soil, the slope of the ground, the elevation of the natural ground water, and the draught of water from the well. A distance of at least 25 feet should be secured with sandy soils, whenever possible, and preferably 50 feet or more. With clay soils, liable to dry and crack, and in limestone regions, liable to contain crevices in the rock, leaching privies should not be used, as wells may be polluted 100 feet or even a mile or more away.

Cesspools are holes dug in the ground to receive not only fecal

matter, but also, perhaps, sink wastes and water-closet discharges. They are often lined with loose stones to prevent caving, but this permits the liquids to leach into the soil. When the soil is sandy there is no objection to this method of disposal; in fact, it is like the method of subsoil disposal previously described, except that the sewage is discharged into the soil below the depth where the soil bacteria are at work. This may be an important difference, however, and the oxidation of the dissolved organic matter proceeds by a slow and incomplete process. Leaching cesspools, however, should not be located near wells used for drinking water supplies. In sandy soils the danger of bacterial contamination is small if the distance is more than 25 feet, but, even so, the idea of

FIG. 141.—FILTER BED WITH SAND RIDGED FOR WINTER OPERATION AT BROCKTON, MASS.

The ice sheet rests on the ridges. The photograph shows the accumulation of suspended matter during the winter.

infiltration of sewage into a well is repugnant, and often the water may be so tainted as to have a disagreeable odor, even when analysis shows it to be bacterially safe.

Ordinarily leaching cesspools should not be constructed in clay soils or in limestone regions, for they are liable seriously to pollute the ground water and are almost sure to overflow. If cesspools are necessary under such conditions they should be made water-tight and treated as septic tanks and the effluent taken care of by subsurface irrigation or some form of land treatment.

In cesspools the organic matter undergoes septic action and the amount of sludge that accumulates is often small. Nevertheless, cleaning is necessary at intervals in the case of all cesspools. The disposal of the contents is one of the most troublesome questions connected with this form of sewage disposal. The common method is to spread it upon

the land as a topdressing. The work is apt to be done in the winter, when other farm work is not pressing, and not infrequently when the ground is frozen. Thus opportunity is given for fecal bacteria of human origin to be washed into a well or some public water supply. If spread on the ground during the summer flies have access to it. If used for fertilizer for crops eaten raw, as celery or lettuce, opportunity is offered for transmission of infection by such foods. The only proper method of disposal for cesspool sludge is by burial or disinfection. In laborers'

FIG. 142.—DISCHARGE OF SEWAGE UPON A FILTER BED AT BROCKTON, MASS.

camp, and in army camps, disposal of fecal matter by cremation is practiced with advantage.

In the South, where hookworm disease is prevalent, the scattering of human fecal matter upon the surface of the ground is one of the greatest elements of danger. The danger of transmission of infection by flies from fecal matter to food is likewise greater in the South, as the warm season is longer, so that greater care needs to be exercised in the construction and care of protected privies than in the North.

## SECTION X

### REFUSE DISPOSAL

By GEORGE C. WHIPPLE

*Professor of Sanitary Engineering in the Harvard Engineering School*

The general term "refuse" is applied to all of the solid waste material not carried by the sewers, such as ashes, rubbish, garbage, street sweepings, manure, and dead animals. The quantity of this waste material that has to be gotten rid of in a city is very large. For example, in the Borough of Manhattan, New York City, the ashes amount to about 1,200 pounds per capita per year, the rubbish 100 pounds, the street sweepings 300 pounds, and the garbage 200 pounds, the total amount of refuse being, in round numbers, a ton per capita per year. In smaller cities the per capita quantities of collected refuse are less than half of this, sometimes considerably less. The amount of garbage alone varies from less than 100 to upward of 200 pounds per capita per year. Both the quantity and character of the refuse vary with the seasons, the maximum amount of ashes occurring in the winter and the maximum amount of garbage in the summer. This fact has an important bearing on the problem of ultimate disposal.

Ashes weigh from 900 to 1,200 pounds per cubic yard, garbage from 900 to 1,100 pounds, street sweepings from 700 to 1,800 pounds, and rubbish from 150 to 250 pounds. The following figures serve to indicate approximately the constituents of the principal classes of refuse:

CONSTITUENTS OF CITY REFUSE

	Water	Volatile Matter	Ash	Carbon	Heat Units per Pound of Refuse B. T. U.
Ashes.....	7-25 %	8-10 %	50-60 %	18-25 %	3,700
Garbage.....	70-80 %	15-25 %	5-15 %	4-8 %	2,000
Rubbish.....	5-15 %	40-65 %	5-15 %	15-40 %	6,000
Street sweepings.	35-45 %	20-30 %	25-95 %	18-25 %	4,000

The refuse problem is to a slight extent a hygienic one, but it is more a problem of economy, convenience, and general cleanliness. Bad smells from fermenting garbage do not directly injure the public health, yet they are an offense, and their elimination is an important matter.

Ashes and street dust may irritate the eyes, nose, and throat and predispose to bacterial infection. Accumulating rubbish is not only unsightly, but may provide conditions favorable for mosquito breeding, while accumulating manure may breed flies. Garbage attracts flies and may breed them if the cans are left uncleaned from week to week, but ordinarily garbage does not stand uncollected long enough to give opportunity for the larvae to hatch.

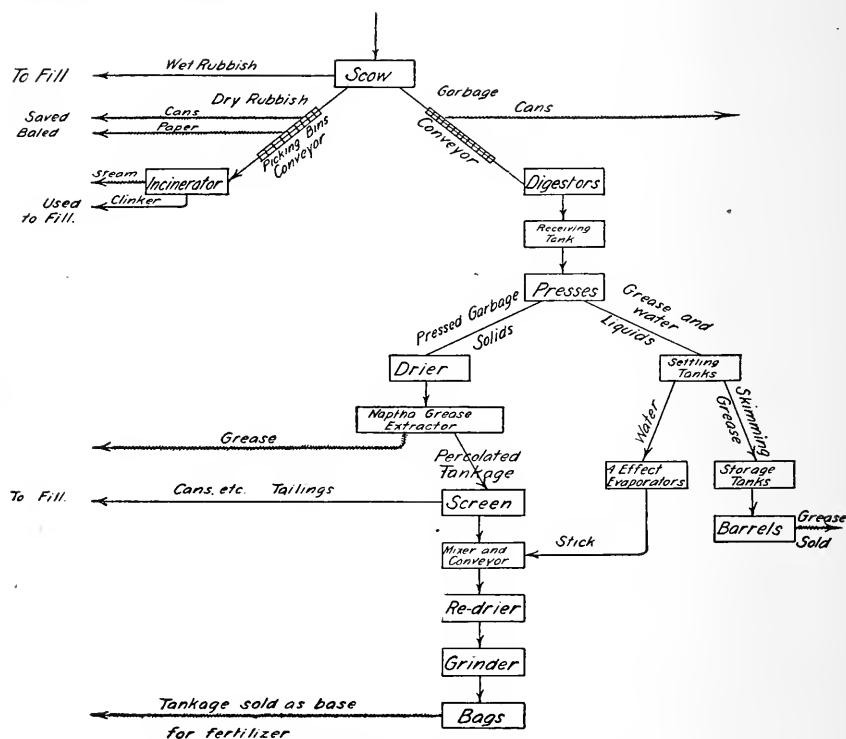

FIG. 143.—DIGESTION PROCESS OF GARBAGE REDUCTION.  
(Boston Development and Sanitary Company)

There are two general methods of collection and disposal of city refuse: the mixed system and the separate system. With the mixed system, which is the one most generally used in Europe, all of the refuse, ashes, garbage, and rubbish is put together by the householder in a single can, conveyed by wagon to the disposal plant, where it is all burned together and the organic matter thus destroyed. The combustible matter in the rubbish and the unburned coal in the ashes are usually sufficient to evaporate the water in the garbage, so that the material is self-consuming. This method is known as incineration, or cremation, or destruction. With the separate system the garbage, rubbish, and ashes are kept separate by the householder and collected in

separate wagons and disposed of in different ways. The ashes are used for filling low land, the rubbish carried to the dump, and the garbage taken to sea and dumped or buried, or fed to hogs, or taken to a reduction plant, where it is cooked and treated for the recovery of fats and other products.

The separate system is commonly used in America, but with numerous combinations of processes of collection and disposal. Whichever method of disposal is adopted determines the manner of collection and the treatment of the refuse by the householder. The choice of the system to be used is one to be determined for each community, largely on the basis of cost. Generally speaking, an incineration plant entails a greater initial outlay than a reduction plant. Its products are ashes and steam. The ashes transported are commonly used for filling near the plant; the steam is used for power to run the works, and the excess steam is sold or converted into electricity and conveyed to places where it can be utilized to advantage. In cities where power is expensive the receipts for the sale of power may be sufficient to throw the balance in favor of this method of disposal. Where power is cheap, however, the opposite may be the case and the reduction process prove the cheaper. With the reduction process the salable products are grease and tankage. The former is sold for soap manufacture, and the latter, which consists of the solid particles of the cooked garbage, is pressed, dried, and ground, and used as a filler for fertilizers. As time goes on other useful products are likely to result from this process, as the materials wasted or sold contain much sugar and proteid bodies.

**Incineration Plants.**—There are two general types of destructors. The mutual assistance type, where there are several grates and divided ash pits, the products of combustion commingling above, thus combining several furnaces into one, and the separate unit type.

The temperature of combustion varies from about 1,200° to 2,000° F. and the capacity is from 1,200 to 1,500 pounds of mixed refuse per day for each square foot of grate surface. Each pound of mixed refuse is capable of evaporating from one to two pounds of water. So-called cremation plants are operated at lower temperatures and are less satisfactory.

The best illustration of an incinerator in this country is the one recently constructed at Milwaukee. This was designed by Dr. Rudolph Hering, and a description of it may be found in the *Engineering News* for July 10, 1910. It has a capacity of 300 tons of mixed refuse per day. The Milwaukee incinerator receives street sweepings and manure as well as ashes, rubbish, and garbage. The manure has been found fully as difficult to burn as the garbage, and on general principles it would appear to be wasteful to dispose of it in that way. With a well-arranged incinerator there are practically no objectionable odors and very little disagreeable smoke.

FIG. 144.—A SIMPLE TYPE OF GARBAGE INCINERATOR.

**Reduction Plants.**—This method of garbage disposal is used in many of our largest American cities, including New York, Boston, Buffalo, the plants as a rule being owned and operated by private companies under contract with the city. Recently an excellent plant of the reduction type has been constructed by the city of Columbus and is now operated by the city. A description of this plant may be found in the *Engineering Rec-*

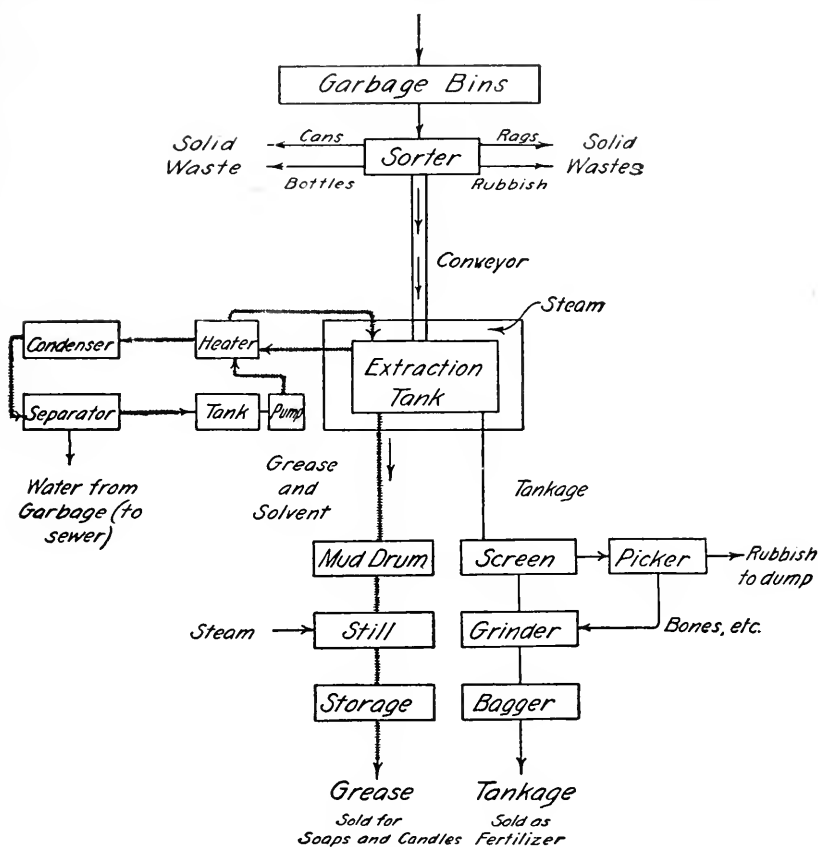

FIG. 145.—COBWELL PROCESS OF GARBAGE REDUCTION, NEW BEDFORD, MASS.

ord of November 19, 1910. When the garbage reaches a plant of this type it is sorted to remove foreign substances, such as tin cans, glass bottles, etc., and conveyed to a series of digestors, where it is cooked for from six to ten hours under pressure of about 60 pounds. It then passes through presses which separate the water and fats from the solid part, called tankage. The water and grease are allowed to pass through settling tanks, where the grease is skimmed off the top. The water flows away to the sewer or is evaporated, and the solids added to the tankage. The latter is sometimes treated for fat recovery by the use of hot naphtha.

Ultimately the tankage is ground and dried and used as a filler for fertilizers. The per cent. of grease recovered may amount to from 1 to 3 per cent. and the marketable tankage to about 20 per cent. of the garbage. Unless a plant of this type is well designed and carefully managed offensive odors will result, but these can be almost completely done away with if proper precautions are taken.

**Feeding Garbage to Hogs.**—In many small cities, especially those of New England, the garbage is fed to hogs. This requires frequent collection and careful management at the piggery. There seems to be no sanitary objection to this method, while it may be a profitable one on account of the large food value of the garbage. Since the World War, this method of disposal has found favor.

**Collection of Garbage.**—From a sanitary standpoint, and even from the standpoint of nuisance, the problem of garbage collection is even a more difficult one than that of garbage disposal. A strong argument in favor of the incinerator method is that the method of mixed collection can be carried on with less nuisance than separate collection. When garbage is mixed with the ashes in a single can the water of the garbage is absorbed by the ashes, fewer flies are attracted to it, and the odor is reduced. The absorption of water by the ashes also tends to reduce the dust nuisance. Mixed collection is also more economical, as fewer carts are required and collections need not be as frequently made. Much depends, however, upon local conditions.

Garbage disposal plants are best located near the outskirts of the city, where no nuisance will result. This ordinarily involves a long haul. If favorable opportunities exist for dumping ashes within the limits of a short haul the separate collection of refuse may prove the cheaper. At Minneapolis the householders are required to wrap each day's garbage in paper. This method is said to be very satisfactory.

## SECTION XI

### VITAL STATISTICS

*The Registration of Births, Deaths, and Marriages, and the Reporting of Notifiable Diseases; the Resulting Records and Derived Statistics; and Their Legal, Social, and Public Health Uses.*

By JOHN W. TRASK

*Surgeon, United States Public Health Service*

*Medical Director, U. S. Employees' Compensation Commission*

[Statistical Methods, see pages 631-638]

Statistics have suffered in reputation because of the seeming truth of the trite statement that one can prove anything by figures. In reality figures are but evidence upon which conclusions may be based. If the evidence is faulty and the faults are not perceived, errors in judgment may result. But this is true of all evidence upon which opinions are based and is no more true of figures and statistics than it is of other kinds of evidence.

Statistics are derived from the collection and numerical classification of observations relating to certain facts or events. They are usually limited to the systematic collection and classification of data relating to relatively large classes of events. In the making of statistics the first and essential step is the recording of observations. After the observations have been noted a numerical compilation of their frequency or of the frequency of certain of their conditions or attributes is possible. The derived statistics, being but a numerical classification or analysis of the recorded events, depend primarily for their usefulness upon the accuracy of the original records of facts. They depend secondarily upon the accuracy of the statistical classification and compilation.

The original notation of facts and of the occurrence of events is usually secured in one of two ways, by enumeration or by registration. In the United States, for example, observations relating to the population are made by enumeration at the decennial censuses. The census enumerators go from house to house and secure certain information regarding each individual. The enumerators are the observers who secure

the original data. Statistics of the population are made by the classification of the information thus obtained and the numerical compilation of the frequency of certain attributes.

On the other hand, the notation of facts relating to deaths is secured by registration. For each individual who dies there is registered with an official known as a registrar of deaths certain information regarding the deceased and the cause and time of death. Here the observers who record the original data are the physicians, members of families, and undertakers. From the classification and compilation of the information thus recorded mortality statistics are derived. Statistics of population depend for their accuracy upon the correctness of the records made by the enumerators and mortality statistics upon the accuracy of the information registered in death certificates.

The statistical method is in itself dependable, although it is true that statistics may be vitiated by the use of inaccurate or incomplete data as a basis or of faulty methods in classification and compilation. Conclusions drawn from statistics by those who attempt to use them may be quite erroneous, but this is more often due to the limitations of the user than to the limitations of the statistics. The most common error in the use of statistics is perhaps the comparing of numerical statements or ratios which are too dissimilar to allow of comparison.

One of the dangers in drawing conclusions from statistics is that the statistics may have been compiled and published by statisticians who were unfamiliar with the accuracy or inaccuracy of the data which they have compiled. The data collected by census enumerators may be incomplete or fictitious as it has been at times for certain communities. The derived population statistics must necessarily be undependable.

Vital statisticians may compile the data of deaths as recorded in death certificates without knowing that the causes of death given may be erroneous in a large proportion of the cases. In such instances the statistics of causes of death must be equally erroneous.

Statistics of birth may be compiled and published and accepted by the unknowing as representing actual conditions. The fact may be that in the state or city under consideration only 80 per cent. or may be only 60 per cent. or 50 per cent. of all births were registered. The derived statistics may therefore be worse than useless, for, while they have the appearance of giving information, what they actually give is misinformation.

Morbidity statistics, statistics of the incidence of disease, may be compiled and published without a clear explanation that the statistics are of the reported cases but that there were many cases that were not reported, the proportion of unreported cases depending upon the disease, the community and the time.

There is a tendency for the statistician to accept the data given to him as being accurate and to compile, tabulate and analyze them as though they in all instances represented facts possible of such handling. The final statistical results are likely to be accepted by the student without a thought of the nature or source or possible inaccuracies of the basic data.

Often the statistician understands the incompleteness and inaccuracies full well and in footnotes and explanatory text explains precisely the nature and extent of dependability of published statistical tables. The reader, however, is prone to pay little attention to explanatory text and to ignore frequently footnotes. A statistical table should always be studied with care and caution and at times critically to an extent bordering on suspicion.

Persons unacquainted with statistical methods are likely to consider statistics as a subject beyond their comprehension. This is a mistaken idea. Most statistical tables are the result of but the simplest of mathematical computations, and are derived usually by nothing more intricate than addition, multiplication and division. Anyone who can comprehend that 350 births during a year in a population of 35,000 persons would be at the rate of 10 births for each thousand of the population can understand most ordinary statistical statements. Familiarity with the meaning of certain of the terms in common use is, however, essential.

To make dependable statistics the original observations and records from which they are derived must be true and accurate, and the classification, compilation, and analysis must be done by competent individuals. The value of statistics when thus handled is daily demonstrated in various social, economic and commercial activities.

## VITAL STATISTICS

**Definition.**<sup>1</sup>—Vital statistics may be defined as statistics relating to the life histories of communities or nations. They pertain to those events which have to do with the origin, continuation, and termination of the lives of the inhabitants. They commonly include statistics of population, births, marriages, deaths, and the occurrence of disease, and the conditions attending these events.

**Development.**—Vital statistics are not a thing of recent origin. Their development to their present form, however, is comparatively modern. The Egyptians, Greeks, and Romans made census enumerations. Some of the ancients, notably the Romans, required also the registration of births and deaths. The statistical treatment of the records was, how-

<sup>1</sup>For statistical methods and definitions of terms, see page 631.

ever, comparatively limited. During the last century and a half, and more particularly the last 50 years, the treatment of vital statistics has been undergoing a rapid evolution. In their present developed form they give a fund of useful information otherwise unobtainable. They have become an essential to every well-organized community and nation. They give a composite picture of the life history of a people which can be secured in no other way. They furnish a means of comparing the life history of one community or people with that of others and of the present with the past.

**Based upon Population.**—All vital statistics are based upon the population. The frequency of births, marriages, sickness, and deaths is expressed in terms of the population, usually as rates giving the number for each 1,000 inhabitants or class of inhabitants. In comparing different communities or different periods, births, marriages, deaths, and the incidence of disease must be based upon a common unit of population. The first requisite to useful vital statistics is statistics of population showing the number of inhabitants, classified according to age, sex, nativity, race, and occupation. It would be desirable, if possible, to have also a classification according to economic status, as birth, sickness, marriage, and mortality rates frequently vary with the incomes of individuals or households. An understanding of population statistics is therefore the primary essential to the comprehension or use of vital statistics, and statistics of population will be first considered.

## POPULATION STATISTICS

**Source of Data.**—The principal source of information regarding population under existing conditions is a census enumeration. For the United States these enumerations are made every 10 years. The last census was taken as of January 1, 1920. In the United States a census has been taken every 10 years since 1790, in Great Britain every 10 years since 1801. In taking a census it is desirable so far as possible to take it at a time when the greatest number of people will be at their usual homes. A midwinter census would find many people absent from the Northern States and an unusual number in southern winter resorts. A midsummer census would find an unusual number at the seashore and at other summer resorts. A number of the States take a census midway between the United States decennial censuses, so that they have an enumeration of the population every five years.

As the only source of definite information as to population is the census enumeration, and as the population is continually changing, in most cases increasing, it is necessary to make estimates of the population for the periods between the census enumerations upon which to

base rates for the various vital events and especially for the accurate computation and expression of marriage, birth, death, and sickness rates.

**Nature of Census Information.**—The taking of a census consists usually of more than a mere enumeration of all persons living at the time the census is taken. It includes the recording of certain information regarding each individual. In taking the 1920 United States census the following information relating to each individual was recorded by States, counties, and townships, villages or cities: Name; address; sex; color or race; age at last birthday; whether single, married, widowed, or divorced; birth and "mother tongue" of the individual and place of birth of his father and mother; year of migration to the United States; whether naturalized or alien; whether able to speak English; the individual's occupation, the kind of work done and the industry or business in which employed; whether an employer, employee, or working on own account; whether able to read and write; whether attending school; whether he owns the home in which he lives.

From the information thus obtained the statistics of population are made. By the classification and numerical compilation of this data it is possible to ascertain the composition and distribution of the population as to sex, color or race, age, marital status, nativity, occupation and literacy.

**Sources of Error in Census Enumerations.**—A certain number of individuals will be enumerated both at the place where they happen to be and at their proper residences. A few will be missed entirely. However, the degree of error thus caused will not be great.

The margin of error in the securing of ages is greater. The age record is customarily intended to be the age in years at the last birthday. The ages given for children under 5 years old are likely not to be accurate due to the tendency to give the age of a child between 6 and 12 months of age as 1 year old and that of a child between 1 and 2 years old as 2 years of age. This tendency to give the age at the next birthday persists up to about the fifth year, although it is perhaps greatest during the first and second years. To avoid the error thus arising, the United States census records the ages of children under two years of age in years and months. For example, a child 6 months of age is recorded as six-twelfths of a year old and a child of 17 months of age as 1  $\frac{5}{12}$  years old.

Women 15 to 20 years of age are prone to give their ages as between 20 and 25 years. Adults over 25 years of age frequently do not know their exact ages and are likely to approximate their ages as being 30 or 40 or 50 years, and to a less extent as 35 or 45 or 55 years. The result is that there is at each census an exaggerated number of ages of 30, 40, 50 years, and also a lesser exaggeration of ages 35, 45, 55, and 65 years.

Individuals over 80 years of age have a tendency to give their ages as greater than they really are.

There is also a considerable margin of error in the recording of occupation. This is due largely to an imperfect understanding of what is wanted and to the multiplicity of occupations and a lack of knowledge as to their proper designation.

**Fluctuation in Population.**—Populations are constantly changing. Individuals are continually being added by immigration. In the United States, and more particularly in some sections of the United States, considerable numbers are annually being added in this way. Immigration is also an important factor in the growth of population in certain South American countries, South Africa, New Zealand, Australia, and Canada.

Populations suffer a continuous diminution by reason of emigration. This is especially true of some European countries.

Migrations may not only affect the population of a country as a whole, but may also alter the distribution of people within a country. There is in many countries a constant movement of people from rural localities to the cities and from one locality to another.

All populations are also being increased by births and suffering losses by deaths. The rate of change, however, resulting from births and deaths is usually comparatively constant or alters gradually, while the changes due to migrations may be exceedingly irregular. The increase in the population caused by the excess of births over deaths is known as the natural increase. A country in which the birth and death rates are equal and in which the factor of migration is negligible will have a fixed population.

The increase of population in certain countries is shown by the following table:

*Showing growth of population of certain countries in millions, 1800 to 1910*

	1800	1830	1860	1890	1910
France.....	27	32	36	38	39
Great Britain and Ireland.....	16	24	29	38	44
Russia in Europe.....	35	45	68	92	..
Austria.....	25	29	34	40	49
Italy.....	17	21	25	30	34
Spain.....	10	11	15	17	19
Belgium.....	..	3	4	6	7
Sweden.....	2	2	3	4	5
United States.....	5	12	31	62	92

**Estimates of Population.**—The frequency of births, marriages, or deaths is usually expressed as the number occurring during the calendar year per 1,000 population. The figures thus given are known as the birth, marriage, or death rates, and are computed upon the mean population—that is, the number of inhabitants estimated to have existed at

the middle of the year, July 1. These estimates are necessary for all dates except those on which census enumerations are made. For the making of estimates there are two principal methods commonly used, known, respectively, as the arithmetical and the geometrical methods. In each method the populations at the last two census enumerations form the known quantities from which the estimates are derived.

*Arithmetical Method.*—In the arithmetical method it is assumed that the increase or decrease in population which occurred between the last two census enumerations took place in equal amounts during each intercensal year (the years between two census enumerations) and will continue to take place annually in like numbers until the next census shall have been taken. Thus, given a city which had a population of 50,000 at the 1900 census (June 1, 1900) and one of 61,850 at the 1910 census (Apr. 15, 1910), the increase during the intercensal period (9 years and 10½ months) would be 11,850, and the annual increase according to the arithmetical method would be

$$\frac{61,850 - 50,000}{9\frac{1}{2}}, \text{ or } 1,200$$

If it is desired to estimate the population as of July 1, 1906, for the purpose of calculating annual rates, this is done by adding to the population as it existed June 1, 1900, the sum of 1,200 for each year intervening between the date of enumeration (June 1, 1900) and the date for which the estimate is to be made (July 1, 1906). There being 6 years and 1 month between these dates, the calculation would be

$$50,000 + (6 \frac{1}{12} \times 1,200) = 57,300.$$

This method assumes the same amount of increase each year and is analogous to the calculation of simple interest. It does not take into account the fact that with the annual increase in population the number of persons of marriageable age and therefore the number of married persons will be greater each year and consequently the number of births. The growth due to natural increases (the excess of births over deaths) is analogous to the increment of compound interest, and where this factor (the natural increase) is the principal one affecting the population growth estimates of population made by the arithmetical method are unsatisfactory, and especially so where the estimate is made for a date several years away from a census enumeration. Where the excess of births over deaths is the controlling factor in population growth the geometrical method of making estimates, being based on the principle of compound interest, is more accurate. Where migration is an important factor in population change, the arithmetical method may be the more accurate. The arithmetical method has been the one found most reliable in the United States and is the method used most commonly in the

past by the Bureau of the Census. The method best adapted to a given population can be ascertained by taking the last two intercensal periods and finding whether the rate of increase during the last intercensal period was, when based upon the increase during the preceding intercensal period, at the rate indicated by the arithmetical or the geometrical method.

*Geometrical Method.*—As previously stated, the geometrical method is based upon the principle of compound interest.

Assuming a decennial census, let

$P$  = population in 1900.

$P'$  = population in 1910.

$r$  = the annual increase per unit of population.

Then the population would be—

$$\text{In 1901} = P(1+r)$$

$$\text{In 1902} = P(1+r)^2$$

$$\text{In 1903} = P(1+r)^3$$

$$\text{In 1910 } (P') = P(1+r)^{10}$$

$$\frac{P'}{P} = (1+r)^{10}$$

$$\sqrt[10]{\frac{P'}{P}} = 1+r \text{ and } r = \sqrt[10]{\frac{P'}{P}} - 1$$

In practice the calculation would be made with the aid of a table of logarithms, and given the value of  $r$  the estimated population for any intercensal or postcensal date is readily obtained. For postcensal dates the estimated population would be—

$$\text{In 1911} = P'(1+r)$$

$$\text{In 1912} = P'(1+r)^2$$

$$\text{In 1913} = P'(1+r)^3$$

$$n^{\text{th}} \text{ year} = P'(1+r)^n$$

The registrar general of England and Wales uses the geometrical method for England and Wales as a whole and a modified method for lesser subdivisions.

However, estimates are after all but estimates and nothing more. For large populations as of entire countries, and for smaller populations not much affected by migration, they are usually sufficiently dependable. In the United States they have been satisfactory for most of the older states and for many of the larger cities. Illustrations of where they have not been dependable are the state of Washington and the city of Detroit. The facts were that the state of Washington had a much more rapid growth in population between the census years 1900 and 1910 than it had between 1910 and 1920; therefore

estimates made in the usual way, subsequent to the census of 1910 and previous to that of 1920, overstated the population. The percentage of error would be greater for each succeeding year. In Detroit the population increase was at a much greater annual rate between 1910 and 1920 than it was between 1900 and 1910. Therefore, estimates based on either the arithmetical or the geometrical method of calculation would have indicated a lesser population than was actually present in the city.

There are other states than Washington where the rate of growth has changed, although probably none where the change has been so great. There are many cities where the change in rate of growth has been as great as in Detroit although this is probably not true of any other city of the size of Detroit.

The estimates of the population for the United States made by the Bureau of the Census are computed by the Geographer of the Bureau. His task is a trying and in a measure an unsatisfactory one, dealing as he does with populations which ebb and flow in unrestricted movement throughout extensive areas. It is only by keeping in touch with the local factors which affect population that the work is possible. For cities, in addition to the actual movements of population, there must be considered the frequent changes in area and boundaries. American cities are continually changing their corporate limits, most of these changes are of the nature of extensions in area and annex populations which had been previously outside the cities.

Estimates of population for intercensal and postcensal years for states and cities of the United States can usually be obtained from the Director of Census. If they cannot be thus obtained it is probably because the data are not available from which a reliable estimate can be computed.

## MARRIAGE STATISTICS

Marriage statistics are of interest because of the information they give regarding the social life of the people and the establishment of families and households, and because of the relation of marriages to population growth through their influence on the birth rate. Their consideration naturally precedes that of birth statistics.

The data for marriage statistics are obtained by the registration of marriages. The common custom in the United States is to require persons desiring to marry to obtain first a license from a designated official. This license is presented to whoever performs the marriage ceremony. The person officiating is required to register the marriage. Those responsible for the completeness of marriage records are therefore in this country usually the clergy and justices of the peace. There is seldom

much difficulty in securing complete records of marriages, and the amount and value of the information given by marriage statistics depend upon the nature and extent of the facts recorded relating to the contracting parties.

In England and Wales marriage statistics are compiled by the registrar general of marriages, births, and deaths. In this country the official responsible for the compilation of marriage records varies in the several States. The United States Bureau of the Census compiled and published in 1909 statistics of the number of marriages and divorces in the United States from 1867 to 1906. It has also compiled the number for the year 1916.

**Marriage Rates.**—Marriage rates may be expressed as the number of marriages for each 1,000 population. While this method gives certain information of a definite character and is useful for comparing different years of the same community and different communities of similar population composition, it is not useful in comparing populations in which the proportion of single persons of marriageable age is not the same. For the purpose of comparing marriage rates, therefore, the more exact method is to express the rate as the number of marriages or persons married for each 1,000 unmarried, divorced, and widowed, of marriageable age, usually those over 15 years of age.

**Factors Influencing Marriage Rates.**—Marriage rates are usually influenced by economic conditions. National prosperity increases the rate, economic depression reduces it. For the same reasons it is influenced by the demand for labor and the rate of wages. The relation of the adopted standard of living to the average wage has a similar effect. In the absence of other factors, the marriage rate is usually a fair index of the relation of average income to standard of living.

The marriage rate may also be affected by the frequency of divorce and remarriage. A high birth rate tends to increase the marriage rate in succeeding years. In communities such as mining towns and new industrial centers the marriage rate may be limited by the presence of a relatively small number of marriageable women.

The marriage rate in a city may be fictitiously high, due to the fact that many couples from the surrounding country and small towns may go there for the purpose of being married, returning then to their homes. In a country affected by emigration a relatively large proportion of the emigrants are apt to be young men and women, the women frequently following after the men have become located. This naturally affects the marriage rate of the home country.

**Uses of Marriage Registration.**—The purpose of the registration of a marriage is largely to protect the home and family. It furnishes reliable evidence upon which to base the legitimacy of children and the dower rights of women.

## BIRTH STATISTICS

Statistics of births are of interest mainly because of their relation to population growth, the excess of births over deaths being known as the "natural increase." Growth of population has been the object of concern to nations largely because of its effect in determining the future military strength and the number of men available for purposes of offense and defense. The practically stationary population of France has for some time been the subject of comment, but with her limited territory it is a question whether the people as a whole are not better off with the present population than they would be with a larger one. More people mean greater congestion and more intense competition. During the last century Great Britain, Germany, Austria, and Russia have trebled in population. Had France done the same, she would now have nearly 80 millions of people, and it is doubtful whether this would have added to the happiness and welfare of the race except that it would probably have been of advantage to her in the late World War and would be an added factor of security for the future.

It is undoubtedly better to have a people proportionate in number to land area and natural resources than to have a teeming population with the consequent economic problems. It would seem more in keeping with modern ethics to strive for a people composed of intelligent, physically sound individuals free from disease and properly housed, fed and clothed, whose days furnished time for both labor and recreation under conditions which conduced to physical and mental welfare and not to deterioration, rather than to strive for mere numbers.

To the health officer and sanitarian birth statistics have only casual interest. Birth registration, however, which furnishes the data from which the statistics are made, is important not only in public health work but in other ways as well.

**Registration in the United States.**—In legislation the registration of births, marriages, and deaths was formerly usually associated and provided for by the same laws. Since 1900, however, this has not been generally true in the United States, where the practice has developed of providing separately for the registration of births and deaths.

A model bill for the registration of births and deaths recommended for enactment by the several State legislatures has been drafted and indorsed by the American Medical Association in consultation with representatives of the Bureau of the Census, the Children's Bureau, the American Public Health Association, the American Bar Association, and a number of other organizations and societies national in scope. The essential features of this law have been adopted by a number of States. It is important that other States should also enact it, for it is without

question as effective a law as any that has been proposed for adoption in this country. It is also highly desirable that the laws of the several States on the subject be uniform, if the Bureau of the Census is to compile the records for statistical purposes. The power to legislate on such matters resides with the individual States. The only means the Bureau of the Census has of preparing national birth and death statistics is to compile the records registered in the several States under State laws. This is done by making copies of the birth and death certificates registered in the various States and from these copies taking the data for statistical tabulations. The adoption of a uniform law would therefore have distinct advantages, even if it were possible for State legislatures individually to draft better ones.

*United States Registration Area for Births.*—A registration area for births was designated by the Bureau of the Census, beginning with the year 1915. The area for 1915 contained the States of Maine, New Hampshire, Vermont, Massachusetts, Connecticut, Rhode Island, New York, Pennsylvania, Michigan, and Minnesota, and the District of Columbia. There have since been added to the area Indiana, Kansas, Kentucky, Maryland, North Carolina, Ohio, Utah, Virginia, Washington, Wisconsin, Oregon, California, Nebraska and South Carolina, making in 1921 a total of twenty-three states and the District of Columbia containing approximately 60 per cent of the total population of the country.<sup>2</sup> The statistics of births have been compiled for this area from transcripts made of the birth certificates filed in the respective States in the same manner that mortality statistics are compiled from State records.

*Source of Data.*—While the data from which population statistics are derived are obtained by direct enumeration, the data from which birth statistics are compiled are gotten by registration. The usual requirement is that whenever a child is born either the attending physician or midwife, or, in their absence, the parents or the head of the household in which the birth occurred, shall register with an official designated for the purpose certain information regarding the child and its parents.

*Nature of Information Secured by Registration.*—The information required to be registered concerning each child born usually includes certain facts relating to the child and the circumstances of its birth, together with certain items concerning the parents. The essential facts are the name of the child, its sex, date and place of birth, and whether born alive or stillborn, and the names and residence of the parents. There are many other items of information concerning births which are of the greatest value and serve various purposes, such as the age, color, nativity, and occupation of the parents, whether the child is a single birth, a twin, or triplet, and whether legitimate or illegitimate.

<sup>2</sup> Rhode Island was dropped from the area in 1919.

These facts are usually required to be stated. The standard certificate of birth for the United States is as follows:

## UNITED STATES STANDARD CERTIFICATE OF BIRTH

(Instructions on certain points may be printed on the back. Size of certificate, 6 1/2 x 7 1/2 inches.)

**MARGIN RESERVED FOR BINDING**  
**WRITE PLAINLY, WITH UNFADING INK—THIS IS A PERMANENT RECORD**  
*N. B.—In case of more than one child of a birth, a SEPARATE ENTRY must be made for each, and the number of each, in order of birth, noted.*

REGISTRAR		11-355 6	

The items registered serve two principal purposes. They serve, first, to identify the child and to establish its age and parentage, and, second, to furnish statistical data.

While in the enumeration of the population the original observer, upon the accuracy of whose work population statistics largely depend, is the census enumerator, in birth registration the original observer, upon whom dependence must be placed, is usually the physician attending at the birth, sometimes the midwife, and in the absence of these the parents.

Births are usually required to be registered with an official appointed for the purpose and known as a registrar. Customarily it is the same official with whom deaths are registered. At times a small fee has been paid to the person making the registration or filling out the certificate. This custom, however, is likely to create in the minds of many the idea that the registration is a matter of discretion—that if the fee is not wanted there is no compulsion to file the certificate and that the forfeiting of the fee annuls the obligation. This is especially true in the United States, where physicians and midwives have in many instances not yet come to realize that the importance of proper registration may mean so

much to the child and its parents that no accoucheur has completed his task nor fulfilled his obligations to the child and its mother until an accurately filled out certificate has been filed with the registrar. The failure to file such a certificate is such a neglect of the interests of both patients, the child and the mother, that it would seem proper to class it with malpractice.

**Birth Rates.**—There are several ways of expressing the birth rate. Each method of statement gives information not given by the others.

*Rate per 1,000 Population.*—The birth rate may be expressed as the number of births occurring during a year for each 1,000 of the popu-

FIG. 146.—BIRTHS (INCLUDING STILLBIRTHS), PERSONS MARRIED, AND DEATHS (EXCLUDING STILLBIRTHS)—REGISTERED PER 1,000 POPULATION PER ANNUM—MICHIGAN, 1871 to 1915.

lation. This is known as the crude birth rate, and is based upon the total estimated mean population for the year—that is, for the calendar year, the population estimated as of July 1. The crude birth rate shows the net result to the community of the several factors governing reproduction—the number of women of child-bearing age, the number of those who are married, the frequency of illegitimacy, etc. In conjunction with the crude death rate it shows the ratio at which the community is reproducing itself by natural increase. It is a quite satisfactory basis for comparing the birth rate of different years for the same community or that of different communities having populations of similar composition. It is unsatisfactory for the comparison of populations having different proportions of females of child-bearing age or of married women—a mining town or new industrial center may have comparatively few

women; a fashionable residential district may have a relatively large female population, most of which consists of unmarried servants.

*Rate per 1,000 Women of Child-bearing Age.*—Birth rates may be expressed as the number of births occurring during the year per 1,000 women of child-bearing age. For this purpose the female population between the ages of 15 and 45 years as determined by census enumeration, or by estimation for intercensal and postcensal years, is taken. The proportion of women of these ages in the population having been ascertained by a census, the same relative proportion is assumed to be maintained until a succeeding census shows a change.

This method gives rates that furnish a much better basis for the comparison of different communities, inasmuch as it gives the births in proportion to the number of potential mothers. It is not, however, satisfactory under all conditions, and the method next described yields more useful information.

*Rate of Legitimate Births per 1,000 Married Women of Child-bearing Age (15 to 44 or 15 to 49 Years of Age) and of Illegitimate Births per 1,000 Unmarried Women of Child-bearing Age.*—In different communities the proportion of married and single women may differ considerably and consequently comparison of their crude birth rates or of rates based on the number of women of child-bearing age would yield comparatively little useful information. The proportion of married women in industrial communities is usually considerably larger than it is in residential suburbs, where there are greater numbers of female servants. To make allowance for these differences in population composition the most useful method of stating the birth rate is in terms of the number of legitimate births per 1,000 married women of child-bearing age (15 to 44 years or 15 to 49 years) and the number of illegitimate births per 1,000 unmarried women of this age.

**Sources of Error in Birth Statistics.**—The principal sources of error in birth statistics are to be found in defective registration. There is no reliable check by which the failure to register births can in all cases be detected. In many foreign countries the people have become accustomed to register births and apparently their returns are quite complete. The registration of illegitimate births, however, is always less complete than that of the legitimate. In the United States the people, as a whole, have in many sections not become accustomed to the registration of births. This is undoubtedly due in part to a rapidly changing population continually receiving large numbers of immigrants from various foreign countries—immigrants who are ignorant of our registration laws and have little opportunity of learning their requirements—and in part to the absence of effort by the authorities to enforce the laws.

As checks upon the completeness of birth registration registrars fre-

† Includes stillbirths.

‡ Year 1912.

quently use the death returns of young children and especially of infants, checking up each recorded death with the birth records to see whether the birth of the child had been registered. The notices of births appearing in newspapers are also often used for the same purpose. If the christenings were required to be notified by those officiating, this too would be of assistance.

**Uses of Birth Registration and Statistics.**—Birth statistics are of use in ascertaining the natural increase of the population (excess of births over deaths). They also give valuable information regarding the effective fertility or fecundity of the race and of the frequency of illegitimacy. These matters are of interest to the economist and the statesman. The possession of birth statistics also furnishes the basis for the present accepted means of stating the infant mortality rate, as will be explained later. The data from which the statistics are made, the registered births, are on the other hand of value to the community in many ways, and to the health officer among others may be especially useful. Some of the uses will be enumerated.

**Legal Records.**—The registration of a child's birth forms a legal record that is frequently useful and may be of the greatest importance. It establishes the date of birth and the child's parentage and legitimacy. It may be required to establish the child's age for attendance at public

schools, for permission to work in States where children below a certain age are not allowed by law to be employed; to show whether a girl has reached the age of consent, whether individuals have attained the age when they may marry without the parents' permission; to establish age in connection with the granting of pensions, military and jury duty, and voting. It may be necessary in connection with the bequeathing and inheritance of property or to furnish acceptable evidence of genealogy, and in fact may be important and useful in possible events too numerous to mention. During the period of mobilization for the late war, there were many instances where the interests of individuals were curiously affected because of there being no dependable record of the time and place of their births.

*Uses in Public Health Administration.*—Registration of births shows where the babies are and makes possible such observance and protection as the health department desires to extend. With birth registration it would be possible for the health authorities to see that the babies are vaccinated against smallpox. This is one of the uses made of registration in England. It would also be possible to see that the babies in poor families have proper food and adequate attention. The observation of infants under two weeks of age would bring to light some cases of ophthalmia which otherwise might cause serious injury to vision and at times total blindness.

**Factors Influencing Birth Rates.**—Birth rates are directly influenced by the number of women, and particularly of married women, of child-bearing age in the population. The child-bearing period of life for women may be considered as that between the ages of 15 and 49 years; the ages between 25 and 44 years are for most races of the north temperate zones, however, those mainly productive.

The economic and social status of the population may also affect the birth rate. In many countries at present the poor families have considerably more children per family than have the well-to-do; in fact to some extent the number of children per marriage seems to be in inverse ratio to the family income. On the other hand, to a degree poor economic conditions are liable to discourage or delay marriage, so that married couples are relatively fewer and older when married, with fewer resulting offspring. The adoption of a more expensive standard of living may produce the same results as depressed economic conditions; fewer and delayed marriages.

The birth rate is also affected by the habits and customs of the people, by their desire to have children or their desire not to have them. Also a high infant death rate is usually accompanied by a high birth rate and, conversely, a low infant death rate by a low birth rate.

**MORBIDITY STATISTICS**

Morbidity statistics are the statistics of sickness and disease. They show the occurrence of diseases and their relative prevalence in different localities and at different times. They differ from mortality statistics in that as relates to disease, mortality statistics are the statistics of fatal cases only, while morbidity statistics include all cases. For example, if in a city there were 500 cases of typhoid fever of which 50 terminated fatally, mortality statistics would deal with the facts relating to the 50 fatal cases, while morbidity statistics would deal with the entire 500.

In the life of the individual, after birth, the next event included in vital statistics which usually occurs is sickness. Disease has perhaps a greater influence in determining the happiness and efficiency of the individual and of the community than any other factor. It also has a direct bearing on the individual's longevity even when in itself not fatal, for every attack of sickness probably does some injury and leaves the human machine impaired to a degree, and an illness occurring a number of years before death may have a far greater influence in determining the duration of life than the terminal illness.

Morbidity statistics have not evolved apace with those of births, marriages and deaths. This is due to the different purposes they serve. The branches which have to do directly with the growth of population were first developed, probably because of the need of the information which they gave in connection with taxation and military enlistment. Morbidity statistics, on the other hand, are contemporary with our comparatively recently acquired knowledge of the causes of diseases and their manner of spread. Their need has been felt only with the advent of present day public health administration, which in turn has been activated in large measure by the story of the causes of death told by mortality statistics.

Morbidity statistics had their origin in the requirement of the notification of cases of certain dreaded diseases, notably smallpox. With the appointment of health officers and the establishment of health departments the notification of other diseases has been required. As knowledge of the causes of diseases and their manner of spread has been obtained and health departments have been faced with the responsibility of controlling maladies found to be preventable, the list of notifiable diseases has grown, for those responsible for public health administration have found that it is impossible effectively to control a disease without prompt information of when, where, and under what conditions cases of the disease are occurring. No epidemiologist would think of attempting to control an outbreak of yellow fever or cholera without inaugurating a de-

pendable system whereby he would receive prompt and accurate information of the occurrence of cases. It is just as impossible effectively to control tuberculosis, typhoid fever, scarlet fever, industrial lead poisoning, or any other preventable disease without a knowledge of the occurrence of cases.

The requirements for notification of the preventable diseases and the extent of their enforcement may be taken as one index of the intelligence and efficiency of health administration in a community.

**Morbidity Statistics in the United States—*Present Status.***—In the United States the authority to require the notification of cases of sickness resides in the respective State legislatures. In some of the States authority has been given to the State boards of health to cover the subject by regulations. In most instances local authorities have the right to supplement the State requirements by such additional ones as may be needed. The laws and regulations of the several States differ widely, as do also the efforts made to enforce them.

The common and most general plan is to require that the original report be made by the physician to the local health officer immediately on diagnosis of the case. The local health officer forwards to the State health department, either immediately or at intervals, a transcript or a summary of the notifications received by him. In a number of States these reports by the local health departments are made to the State authorities daily, in some weekly, in several States monthly, and in a few States at longer intervals. In the States in which the reports are made daily the State health department is in a position to keep constantly informed regarding the prevalence of the notifiable diseases. The same is in less measure true when the reports are made weekly. When the reports are made at longer intervals the current value of the information to the State department is largely lost.

In certain States physicians have been required to report the notifiable diseases directly to the State health department. This, in effect, makes the State health officer also the local health officer and responsible for the control of the notifiable diseases, the control of disease and the notification of cases being inseparable, the latter giving the necessary information by which to direct action in the former.

In some States the laws relating to morbidity reports specify that cases of certain classes of disease shall be notifiable. These classes have been variously stated, the wording being in some instances that "all cases of contagious or infectious diseases dangerous to the public health shall be reported," in others "all communicable diseases," or "all contagious diseases," or "all diseases dangerous to the public health." When the requirements have been stated in general terms in this way their enforcement has been especially difficult unless the diseases included have been specifically enumerated.

The following named diseases are those specified by the various State requirements, with the number of States in which each is notifiable: \*

**The Model State Law for Morbidity Reports.**—Since each State has exclusive authority within its jurisdiction over the requirements for the notification of disease, any comprehensive plan that may be developed for morbidity reports and morbidity statistics must be the result of combined effort and coöperation and the enactment by the several States of similar requirements. It implies also an adequate enforcement of these requirements. The question of State morbidity reports is one of the most difficult problems to be solved by the State authorities. A number of States have been endeavoring earnestly to solve the problem within their respective jurisdictions. Considerable progress has been made in several instances. The question is an important one, and is bound to receive much consideration in the future. The State health authorities in conference with the Public Health Service had the matter under consideration for some time and in June, 1913, approved a model State law for morbidity reports. The model law makes the occurrence of cases of the following-named diseases and disabilities notifiable:

## GROUP 1.—COMMUNICABLE DISEASES

Actinomycosis.	Paragonimiasis (endemic hemoptysis).
Anthrax.	Paratyphoid fever.
Chickenpox.	Plague.
Cholera, Asiatic (also cholera nostras when Asiatic cholera is present or its importation threatened).	Pneumonia (acute).
Dengue.	Poliomyelitis (acute infectious).
Diphtheria.	Rabies.
Dysentery:	Rocky Mountain spotted or tick fever.
(a) Amebic.	Scarlet fever.
(b) Bacillary.	Septic sore throat.
Favus.	Smallpox.
German measles.	Syphilis.
Glanders.	Tetanus.
Gonococcus infection.	Trachoma.
Hookworm disease.	Trichinosis.
Leprosy.	Tuberculosis (all forms, the organ or part affected in each case to be specified).
Malaria.	Typhoid fever.
Measles.	Typhus fever.
Meningitis:	Whooping-cough.
(a) Epidemic cerebrospinal.	Yellow fever.
(b) Tuberculous.	
Mumps.	
Ophthalmia neonatorum (conjunctivitis of newborn infants).	

## GROUP 2.—OCCUPATIONAL DISEASES AND INJURIES

Arsenic poisoning.  
 Brass poisoning.  
 Carbon monoxid poisoning.  
 Lead poisoning.  
 Mercury poisoning.  
 Natural-gas poisoning.  
 Phosphorus poisoning.  
 Wood alcohol poisoning.

Naphtha poisoning.  
 Bisulphid of carbon poisoning.  
 Dinitrobenzine poisoning.  
 Caisson disease (compressed-air illness).  
 Any other disease or disability contracted as a result of the nature of the person's employment.

## GROUP 3.—MISCELLANEOUS DISEASES

Beriberi.  
 Cancer.  
 Continued fever lasting seven days.

Drug addictions or habits.  
 Pellagra.

**The Results of Notification in Certain States and Cities.**—The completeness of the reports of the notifiable diseases in States and cities in which there is registration of deaths may be estimated with some degree of accuracy by comparing the number of cases reported with the number of deaths registered as due to the same cause. In doing this, however, it must be borne in mind that we do not know the fatality rates of many diseases, for up to the present time there have seldom been satisfactory morbidity records of sufficiently broad application to permit of the determination of such rates, and it must also be remembered that the fatal-

*Diphtheria, measles and typhoid fever—Cases reported, deaths registered, indicated case rates per 1,000 population, indicated fatality rates per 100 cases, and number of cases reported for each fatality registered, in certain cities, 1917.*

ity rates of many diseases vary in different epidemics, and from year to year, and with the season and geographic location.

To see the possibilities of notification and the results being obtained in certain diseases in those States and cities in which notification has been developed to a degree approaching most closely one that is satisfactory, refer to the table on page 1246.

**Source of Statistical Data.**—The manner of collecting the data from which morbidity statistics are compiled is closely allied to the registration method used for births. The data consist of the reports of cases of

FIG. 147.—DIPHTHERIA.

Number of cases notified per annum for each death registered—Michigan, 1884 to 1912.

disease made usually by physicians and in some instances by the heads of families and households. The original observers then, upon whom morbidity statistics depend chiefly for their completeness, are the practicing physicians. This is necessarily so, for neither the health department nor any other branch of government can keep in such close touch with the lives of the people as to be in a position to know of the occurrence of disease. The physician is the one who, because of the very nature of his work and his relation to the community, is best able to have this information and furnish it. He comes in contact with the sick to a degree others do not. The health officer cannot know of the presence of disease except as it is reported to him by physicians. Experience has shown that there may be hundreds of cases of a dangerous infection in a city and the health officer not know of its presence in the absence of notification.

Unfortunately many practicing physicians have little knowledge of the methods of health administration and in common with people in general frequently expect the health department in some mysterious man-

FIG. 148.—SMALLPOX.

Number of cases notified per annum in Michigan from 1883 to 1915.

ner to control disease without placing upon them the burden and privilege of coöperating by the notification of the occurrence of cases. The practicing physician, whether he recognizes it or not, or is so recognized

by the community, is essentially an adjunct of the health department, for, unless he performs his part, the health department is in large measure helpless.

FIG. 150.—SCARLET FEVER.

Among practicing physicians, at least in the United States, there has at times been the feeling that the knowledge of a disease in a patient is privileged information which they should not be called upon to impart. In communities where the laws require the notification of the disease this feeling has no legal basis and the physician who does not make report is not a law-abiding citizen. But aside from the legal aspects of the matter there would seem to be little justification for such a course. Every physician has a number of individuals or families who look to him, and properly so, not only for treatment, but also for such reasonable protection from disease as he is able to give. The failure to report the occurrence of a case of communicable disease in one patient may lead to its spread to others among his clientele whose rights he has ignored. He therefore violates the intent and spirit of the ethical principle of the protection of patients among whom must be considered the well together with the sick. The notification of disease is in the interests and for the protection of the community, and as his patients are members of the community their interests are ignored and, because of the anti-social whim or supposed convenience of the individual affected with a notifiable disease, they are deprived of the protection they have a right to expect. It would seem that the physician who fails to report his cases of preventable diseases required to be notified may properly be considered as actively obstructing public health administration.

Related in thought is the following quotation from an address by Prof. Victor C. Vaughan:<sup>3</sup>

In the future the training of the medical man must be developed largely with a view to his broader relations to the public. His proper function must be to prevent, rather than cure disease. The physician's duties are to become more and more largely official in the sense that his services are to be rendered to the community, and not exclusively to the individual.

The health department laboratory may be, and in many places is, an important factor in giving information of the occurrence of cases and prevalence of certain diseases. By having a diagnostic laboratory with a trained personnel at the service of the practicing physician the health department becomes not only a consultant performing gratuitous service for the physician but at the same time secures early and accurate information of many cases which otherwise might not be properly diagnosed and therefore not reported. A record of every positive diagnosis made by the laboratory should be sent to the epidemiological bureau, or other division of the health department responsible for the control of disease and should for purposes of morbidity records constitute notification of the case when accompanied by such necessary information as the name, age, sex, and address of the patient. There would seem to be no good reason why the services of the health department should not

<sup>3</sup> *Pennsylvania Medical Journal*, November, 1913.

be at the disposal of the community for the diagnosis of all diseases.

**Nature of Information Secured by Morbidity Notification.**—It is the practice for health departments to furnish to physicians notification blanks upon which the reports are to be made. In some instances these are in the form of post-cards, which have proper spaces indicated for notation of the required information. These cards require the physician to affix a stamp before mailing them to the health department. A far better practice is that employed by many States and cities of supplying physicians with postal-card forms which do not require additional postage before mailing.

The information relating to the reported cases which physicians are required to give varies in the several States. It has been customary to require the physician, in making his report, to include all the data regarding the case desired by the health department. In the majority of instances no further data regarding these cases are secured by the health officials. While it may be impracticable in most instances to change this practice at the present time, it must be recognized that a local health department should prefer to collect its data regarding each case itself, and should not be willing to depend upon the physician's report for its epidemiologic information. Logically, the only information which the physician should be depended upon to give in his report is the occurrence of a case, or a suspected case, of a given disease in such and such a person at such and such an address. He might properly be required to add to this such data as are matters of record or easily verified, such as the age, color, and sex of the patient, and similar information. The local health department, however, should be reluctant to depend upon the diagnosis of the practicing physician, unless the diagnosis has been verified by a trained diagnostician in the service of the department itself. This has been the practice during recent outbreaks of such diseases as yellow fever and plague. It is also the practice in certain other instances. It must necessarily become the practice whenever a determined effort is to be made in the control of any preventable disease.

**The Standard Notification Blank.**—The standard notification blank approved by the State and Territorial health authorities of the United States in conference with the Public Health Service at their tenth annual conference in June, 1913, calls for the following information:

1. Date.
2. Name of disease or suspected disease.
3. Patient's name, age, sex, color, and address. (This is largely for purposes of identification and location.)
4. Patient's occupation. (This serves to show both the possible origin of the disease and the probability that others have been or may be exposed.)

5. School attended by or place of employment of patient. (Serves same purpose as the preceding.)
6. Number of persons in the household, number of adults and number of children. (To indicate the nature of the household and the probable danger of the spread of the disease.)
7. The physician's opinion of the probable source of infection or origin of the disease. (This gives important information and frequently reveals unreported cases. It is of particular value in occupational diseases.)
8. If the disease is smallpox, the type (whether the mild or virulent strain) and the number of times the patient has been successfully vaccinated, and the approximate dates. (This gives the vaccination status and history.)
9. If the disease is typhoid fever, scarlet fever, diphtheria, or septic sore throat, whether the patient had been or whether any member of the household is engaged in the production or handling of milk. (These diseases being frequently spread through milk, this information is important to indicate measures to prevent further spread.)
10. Address and signature of the physician making the report.

These reports are to be made on postal cards furnished for the purpose and mailed immediately to the local health department, so that proper measures can be taken to prevent the spread of the disease or to find the focus or source from which the case originated, that the occurrence of additional cases may be prevented. These reports are then to be forwarded to the State department of health, but before being forwarded the local health department is to note thereon:

1. Whether the case was investigated by the local health department.
2. Whether the nature of the disease was verified.
3. What measures were taken by the local health department to prevent the spread of the disease or the occurrence of additional cases from the same origin.

**Sources of Error in Morbidity Statistics.**—The errors in morbidity statistics of civil populations are due principally to incomplete notification—that is, to the failure of physicians to report all cases of the notifiable diseases. More cases of disease usually occur than are reported. This can never be entirely overcome, for many diseases vary in severity under different conditions, and some cases are so mild that their true nature is not recognized, and frequently they do not come to the attention of physicians.

The cases notified are usually correctly diagnosed, for physicians do not generally report cases until they are practically sure of the diagnosis, as the case remains an evidence of faulty diagnosis if a mistake is made. Then, too, physicians naturally wish to report only

those cases required and to know whether a given case is one of these he must first be reasonably sure of his diagnosis.

The errors in morbidity statistics are therefore chiefly those of incompleteness. In this they resemble birth statistics, although the degree of incompleteness, due to the difference in the nature of the two, is usually greater in morbidity statistics.

They differ from mortality statistics, in which the principal source of error is incorrect statements of cause of death. Due to the control possible over the disposal of bodies of the dead, it is not difficult in most communities to obtain practically complete registration of deaths. It is, however, exceedingly difficult to secure correct statements of the causes of death. The physician feels compelled to give a diagnosis in each death certificate and usually does so even when he is uncertain of the nature of the malady, realizing probably that the body will be buried and that there will be nothing to show the error if one is made.

The tendency is then in morbidity reports for the diagnoses to be correctly given, but not all cases reported, while in the registration of deaths the tendency is for the recording of practically all deaths but the filing of many incorrect statements of the causes of death.

**Uses of Morbidity Reports and Statistics.**—In health administration, morbidity reports—that is, reports of cases of sickness—serve several purposes, which may be briefly stated to be as follows:

1. In the communicable diseases morbidity reports show the occurrence of cases which constitute foci from which the disease may spread to others, as in scarlet fever, typhoid fever, tuberculosis, or yellow fever, and make it possible to take proper precautions to protect the family of the patient, his associates, or the community at large.

2. In some diseases morbidity reports make it possible to see that the sick receive proper treatment, as in ophthalmia neonatorum, diphtheria, and, in certain cities, tuberculosis. The reporting of cases of ophthalmia in the newborn makes it possible to save the sight of some infants who would otherwise not receive adequate treatment until after much damage had been done. In diphtheria the health department can be of service in furnishing antitoxin. Some cities furnish hospital or other relief to consumptives who would otherwise be without proper treatment.

3. In diseases that are not communicable, such as those due to occupation or environment, reported cases show the location of conditions which are causing illness or injury. This makes it possible to remedy the faulty conditions, so that others may not be similarly injured.

4. In certain diseases, of which the cause or means of spread is unknown, morbidity reports show their geographic distribution and varying prevalence and the conditions under which cases occur. This

information has great potential value in attempts to ascertain their causes and means of spread.

5. Reports of the occurrence of disease are necessary to show the need of certain sanitary measures or works and to control and check the efficiency of such measures or works when put into operation. In pulmonary tuberculosis such reports show the number of consumptives in the community and the need of sanatoria. In malaria they show the prevalence of the disease, the need for drainage and other anti-mosquito work, the efficiency of such work when in operation, and when a change in the prophylactic measures or additional ones are necessary. In typhoid fever they show faults in the water supply or in the control of the production and distribution of milk or in the disposal of excreta in special localities.

6. Morbidity reports when recorded over a period of time and properly compiled become a record of the past occurrence of disease. They show the relative prevalence of disease from year to year and under varying conditions. They show the effect of the introduction of public-health measures and of sanitary works. They give a history of disease not obtainable in their absence.

**Morbidity Rates—Crude Morbidity Rates.**—Morbidity rates may be expressed as the number of cases of a given disease occurring during a year per 1,000 of the total population, or the rate may be expressed as the number of cases per 10,000 or per 100,000 population. These are crude rates. Giving the rate per 1,000 population has the advantage of employing the same population unit as that used for expressing birth, marriage, and death rates. It has, however, what has been considered by some a disadvantage, namely, that the rates will frequently be expressed by fractions where the 1,000 unit of population is taken as the basis. For this reason 10,000 and 100,000 population units have often been used.

*Specific Morbidity Rates.*—Diseases limited entirely or principally to certain ages or to certain classes of the population should be expressed also in rates of the number of cases per 1,000 persons in the population of that age or class. Diseases limited to childhood should be expressed as rates per 1,000 children; diseases limited to women should be expressed as rates per 1,000 women. Occupational disease rates should be expressed in terms of the number of cases per 1,000 persons employed. These are specific rates.

Specific morbidity rates showing the incidence of disease by age groups, sex, occupation, and economic or social condition will be possible with the improved notification methods which are being gradually adopted.

*Case Fatality Rates.*—The case fatality rate of a disease is usually expressed in terms of the number of deaths per 100 cases;

that is, as the percentage of cases which terminate fatally. For example, if out of 100 cases of typhoid fever 10 die, the case fatality rate is 10 per hundred or 10 per cent. In calculating fatality rates it is to be borne in mind that among cases reported during one week, month, or year, all or part of the fatal terminations may occur during a succeeding week, month, or year.

**Hospital Statistics and Sickness Insurance Records.**—In a number of foreign countries much valuable information regarding sickness rates, aside from that of the commonly notifiable diseases, is being secured from the workmen's sickness insurance records. In some countries hospital statistics are compiled and furnish data of much value. Bolduan<sup>4</sup> suggested a plan for compiling hospital morbidity statistics in this country. The method is especially applicable to the hospitals of a large city, but might be used for the hospitals of an entire State and is capable of being made nation-wide in scope. The essential feature of the plan is the filling out of "discharge certificates," analogous to ordinary death certificates, on the discharge of each patient from a hospital. These discharge certificates are then to be sent to a central filing bureau, preferably the health department, and there classified and analyzed.

It is also especially desirable to have statistics of the insane and mentally defective. New Jersey has enacted a law requiring the notification of cases of mental deficiency and of epilepsy.

**Factors Influencing Morbidity Rates.**—The factors which influence morbidity rates and the prevalence of sickness are the manifold direct and indirect causes of disease. There are certain widely acting indirect factors which increase morbidity by lessening individual resistance. There are other factors which are specific for individual diseases. In malaria the direct cause is infectious anopheline mosquitoes, and the indirect cause swamps and stagnant water in which the mosquitoes breed. The factors influencing typhoid fever rates are commonly the milk supply, the water supply, the manner of disposal of excreta, presence of flies, the extent to which houses are screened, personal and social habits, etc. In an industrial community the morbidity from occupational diseases and from diseases caused indirectly by the conditions attending certain kinds of labor constitutes a factor the importance of which is beginning to be realized.

**Notification of Occupational Diseases.**—Most civilized nations have during the last hundred years undergone an industrial evolution. It has been within this period that the large factory with its hundreds or thousands of workers has had its development and that many of our present industries and the majority of our industrial processes have been

<sup>4</sup> Bolduan, Charles F.: "Hospital Morbidity Statistics," *New York Medical Journal*, March, 1913, p. 643.

developed. So great has been this change in the industrial life of the people that there has been developed a new and important branch of hygiene and sanitation which is properly termed industrial hygiene. With this industrial development there have evolved new diseases and disabilities due to the nature of the individual's work or to the conditions incident to the work. Not only have new diseases in a sense been evolved, but a number of diseases previously rare have become much more common. Under existing social conditions a large proportion of the people are engaged in some occupation, and the diseases of occupation merit the attention and consideration of the community.

The control of occupational diseases has during the last few years been receiving much consideration. Naturally the first step in the control of the industrial diseases was the securing of a means by which the occurrence and prevalence of these diseases might be known to those whose duty it would be to control them. For this purpose, and largely because of the activities of the American Association for Labor Legislation, a number of States have since 1911 enacted laws requiring the notification of certain occupational diseases.

A number of State laws require cases of occupational diseases to be notified to the State health department, and others require the notifications to be made to the State labor office. The results of notification have not been as yet satisfactory. This may be due to the newness of the idea to the physician of considering whether a disease is occupational in origin. The medical schools have given little attention to the subject. It is highly important to the practicing physician that he have a knowledge of the industries of his community and of the diseases and disabilities they are likely to cause. The proper and successful treatment of patients necessarily depends upon a knowledge of the direct or indirect cause of the individual's ailment, and in an industrial community this will depend frequently upon a knowledge of occupational diseases.

A number of States have enacted laws which should in a way be much more successful in bringing to light the occurrence of these diseases (Illinois, Missouri, Ohio, and Pennsylvania). The plan referred to is that of requiring certain industries to have their employees examined physically by competent physicians at stated intervals to ascertain whether there exist in the employees any ailments or disabilities due to the nature of their occupation. The physicians making these examinations naturally become in time expert, if they are not so in the beginning, and the examination of the employees in this way will guarantee the finding of a large proportion of the cases of industrial diseases, in most instances in their earlier stages. If the occupational diseases are to be controlled, it is necessary that the occurrence of cases be ascertained in some way, for the occurrence of each case shows the existence of conditions which have produced disease in one employee

and will in all probability produce it in others. Each case notified shows a danger spot.

**Morbidity Statistics of Military Populations.**—Military organizations offer a much better opportunity for the recording of morbidity data than do civil populations. In military organizations all persons are under constant supervision and all but the most trivial illnesses become a matter of record. This includes not only the cases of those diseases which are ordinarily reportable among civil populations but cases of other illnesses and disabilities as well. The limitations of military morbidity statistics are confined largely to the question of diagnosis, but even the dependability of diagnosis is probably greater in military organizations because the medical officers are a selected group and because of the added measures of control.

Military morbidity statistics may be exceedingly useful in determining the geographic distribution, and in a measure the relative prevalence, of certain diseases throughout the country. They may be of particular value for this purpose in localities where these diseases are not reportable or are at best very incompletely reported among the civil population. Thus records of the incidence of malaria at military posts and camps will give information not otherwise obtainable of the prevalence of this disease. This is particularly true under conditions existing in times of peace, and is illustrated by the records of the troops at Fort Washington. Fort Washington is in Prince Georges County, Maryland, about 12 miles south of the city of Washington. For several years up to 1913 the troops at Fort Washington had the highest malaria rate of any army post in the United States. The malaria admission rate had varied from 736 per 1,000 strength in 1906 to 172 per 1,000 in 1912. And yet during this same period the morbidity records of the state of Maryland showed practically no malaria in Prince Georges County. This was so notwithstanding the fact that at the time the morbidity records of the state as regards other diseases compared very favorably with the better records of civil populations in other states. However, the civil records of Maryland gave no idea whatsoever of the prevalence of malaria and had the disadvantage of appearing to give information when they did not.

The value of military morbidity records to show the geographic distribution of disease is limited, however, largely to diseases which are endemic or pertain particularly to localities of which malaria is one of the most typical.

Some of the terms used in stating morbidity data of military groups differ from the corresponding terms used for civil populations. Thus in the Navy the population of a vessel or other Naval unit is known as the "Complement." In the army the military population of a camp or other military group is commonly termed the "Strength."

*Admission Rate.*—Ordinarily in military organizations every person reporting ill or disabled is considered as “admitted” to the sick list and the total number so reporting constitutes the total admissions. For some ailments a soldier or sailor may apparently recover and be discharged from the sick list, but have relapses and be readmitted in some instances several times. To this extent the total admissions do not show the total number of cases of disease or disability. The first admission of an individual for a case of illness constitutes the original admission and the subsequent admissions for the same illness or disability are “readmissions.” The number of original admissions therefore gives the number of actual cases. The term “admission rate” corresponds to the term “morbidity rate” as used for civil populations, and is usually expressed as the number of original admissions during a year for each 1,000 of the “complement” or “strength” just as civil morbidity rates are expressed as the number of cases recorded during a year per 1,000 population. Thus an admission rate of 640 would mean that there had been 640 cases of illness or disability during the year for each 1,000 of the military population. This would be the crude admission rate. Admission rates might be given for classes of disease or disabilities or they might be given for special classes of the military population. These would be specific admission rates. This is illustrated by the following two tables, one taken from the naval bulletin issued March 15, 1919, the other from the annual report of the Surgeon-General of the Army for the year 1917.

MORBIDITY RATES—NAVY

Entire Navy	1913 (65,926)	1914 (67,141)	1915 (68,075)	1916 (69,294)	1917 (245,580)	Combined rate for the five-year period (combined complement 516,016)

organization thus unavailable for duty is known as the noneffective rate, and is expressed as the average daily number noneffective per 100 or per 1,000 of the "complement" or "strength."

## MORTALITY STATISTICS

Mortality statistics are statistics of deaths. They are of interest primarily because of their relation to changes in population. Aside from the factor of emigration, mortality statistics show the losses in numbers being sustained by the population, just as birth records show the additions. Where migration is a factor having an appreciable effect upon population it likewise merits statistical consideration, for it, too, represents population gains and losses.

Mortality statistics have performed another important service in creating an interest in public health administration and securing support for sanitary measures. They show the extent of the loss by death caused by diseases. In the absence of morbidity records they have also frequently been used as an index of the prevalence of certain infections. It has been possible to use mortality statistics for the latter purpose on the assumption that the fatality rates of disease are fairly constant. However, we should bear in mind what Newsholme has said:

"The registration of deaths gives a very imperfect view of the prevalence of disease. \* \* \* It is fallacious to assume any fixed ratio between sickness and mortality. The fatality of a given infectious disease varies greatly in different outbreaks under varying conditions. The

highest ratio of sickness is occasionally found associated with a favorable rate of mortality."

This absence of fixed fatality rates is shown by the experience in the United States with smallpox, in which the ratio of deaths to cases has varied from 1:1,000 to 1:3; measles, in which the ratio of deaths to cases has been from 1:800 to 1:20; typhus fever, including "Brill's disease," in which it has varied from 1:5 to practically no fatality; and typhoid fever, in which the ratio has varied from 1:24 to 1:5.

**Registration of Deaths in the United States.**—The history of the registration of deaths in England and the United States is coupled with that of marriages and births. In the United States dependable registration was first enforced in Massachusetts and New Jersey. Other States have had laws of various types, mostly inadequate. Only recently have any number of States secured anything like complete registration. The bringing about of accurate death registration in the United States is due largely to the efforts made by the Bureau of the Census, and especially to the untiring efforts of Dr. Cressy L. Wilbur, formerly chief statistician, Bureau of the Census.

**United States Registration Area for Deaths.**—The registration area for deaths established by the United States Bureau of the Census includes the States, and cities in other States which effectively enforce satisfactory registration laws, and, in the opinion of the Director of the Census, have at least 90 per cent. of all deaths registered. This area was first established in 1880 and at that time included Massachusetts, New Jersey, and certain cities in other States. The States included March, 1921, and the dates when admitted to the area were:

DEATH REGISTRATION AREA—STATES

## DEATH REGISTRATION AREA—CITIES

*(in non-regulation areas)*

Atlanta, Georgia.	Galveston, Texas.
Augusta, Georgia.	Houston, Texas.
Beaumont, Texas.	Mobile, Alabama.
Birmingham, Alabama.	Montgomery, Alabama.
Brunswick, Georgia.	Oklahoma City, Oklahoma.
Cleburne, Texas.	San Antonio, Texas.
Dallas, Texas.	Savannah, Georgia.
El Paso, Texas.	Wheeling, W. Va.
Fargo, North Dakota.	

This made a total of 34 states, the District of Columbia and the Territory of Hawaii and 17 cities in nonregistration states containing in all approximately 82 per cent. of the country's population.

**Source of Data.**—The original information from which mortality statistics are derived is obtained by the registration of deaths. This is commonly accomplished by the use of a blank or schedule prepared for the purpose and in this country known as a death certificate. The model law for the registration of births and deaths provides that no body shall be interred or otherwise disposed of or removed or temporarily held pending further disposition "more than 72 hours after death unless a permit for burial, removal, or other disposition thereof shall have been properly issued by the local registrar of the registration district in which the death occurred or the body was found. And no such burial or removal permit shall be issued by any registrar until, wherever practicable, a complete and satisfactory certificate of death has been filed with him. . ." This insures the making of a death certificate and its registration in each instance of death unless the body is sur-

reptitiously and illegally disposed of. It therefore guarantees practically complete registration. In the rural districts of some localities bodies are frequently interred in private burial grounds and on farms in some chosen spot on the premises. Under these conditions bodies would occasionally be buried without registration, due to ignorance of the law.

**The Standard Death Certificate.**—The standard death certificate in use throughout the registration area for deaths calls for the following information:

Place of death.

Name, sex, color, race, conjugal condition, age, date of birth, occupation, and birthplace of decedent, name and birthplace of father, maiden name and birthplace of mother.

Signature and address of informant giving preceding information.

Date and time of death and a statement as to the duration of medical attendance, on the decedent, the cause of death, and its duration, and certain other data are to be given by the physician, if any, last in attendance.

The date and intended place of burial and the address of the undertaker are to be given over the undertaker's signature.

The date when the certificate is filed is inserted by the registrar with his signature.

The style and form of the standard certificate of death used in the United States is shown on page 1263.

The responsibility of seeing that a certificate is properly made out and filed with the registrar rests primarily upon the undertaker, according to the provisions of the model law.

**Sources of Error.**—In the use of mortality statistics as well as other statistics erroneous and unwarranted conclusions are sometimes arrived at by attempting to compare incomparable data. Mortality rates secured by lax enforcement or faulty methods of registration cannot properly be compared with those based upon complete registration. Nor can the rates of communities with populations of different sex and age composition be compared unless proper allowances are made and the rates expressed in terms of the same population. For example, it is improper to compare the mortality rate of an aggregation of young men picked for physical soundness, such as an army or navy, with the crude or general mortality rate of a civilian population. The nearest means of making comparison would be to compare the rate of the picked body of men with the rate among men of the same age groups in the civil population. But even this would be faulty, for the one group would consist of men specially picked for physical fitness while the other group would include the fit and the unfit, the strong and the weak. Nor is it possible to compare the mortality rate of any special

population group with the rate of the population from which it has been derived by intentional or other process of selection unless the differences in population composition are considered. Thus, it would give little information of value regarding the effect of locality and environment upon the duration of life to compare the mortality rate of New York City or the registration area of the United States with that of the Canal Zone during the construction of the canal without taking into ac-

MARGIN RESERVED FOR BINDING

N. B.—WRITE PLAINLY WITH UNFADING INK—THIS IS A PERMANENT RECORD. Every item of information should be carefully supplied. AGE should be stated EXACTLY. PHYSICIANS should state CAUSE OF DEATH in plain terms, so that it may be properly classified. Exact statement of OCCUPATION is very important. See instructions on back of certificate.

count any differences which may have been produced in the age and sex composition of the two populations by the selective process naturally operating in the case of the Canal Zone. For the same reason there is little to be gained by comparing the mortality rate of any American city or State with that of the civil employees of the Philippine Islands or any other similar group unless based upon an analysis of age and sex composition of the populations.

Another possible source of error in mortality statistics which requires to be considered is the original data contained in the death certificates from which the statistics are compiled. The personal and statistical particulars usually furnished by some member of the family are undoubtedly in most instances accurate with the exception of the state-

ment of occupation of the decedent, which offers unusual difficulties, due to the indefiniteness of many of the terms commonly used in so far as showing the exact kind of work is concerned. This is due in some measure to the fact that the nomenclature in common use has not progressed apace with the rapid development of new industries and industrial processes and methods. Whereas 50 years ago the statement of occupation would have been in most cases comparatively simple and easily understood, today with changed industrial conditions the matter requires greater precision if useful statistical information is to result.

Perhaps the most common error entering into death registration, and therefore into mortality statistics, is in connection with the statement of cause of death. Aside from the fact that in the instances in which it has been impossible for the attending physician to feel reasonably certain as to the nature of the terminal illness a cause of death is nevertheless usually stated in the certificate, and also the fact that at times the physician knowing the nature of the illness may, in the belief that he is shielding the family from odium or because of their whim, intentionally state an erroneous cause of death, there still remain the many unavoidable errors of mistaken diagnosis. Just how great a factor this last may be it is difficult to estimate.

However, the findings of Dr. Richard C. Cabot<sup>5</sup> give at least a hint of its possible importance and the extent to which it may affect that part of mortality statistics relating to causes of death. In a study of 3,000 autopsies with regard to the relation of the actual cause of death as found post mortem to the clinical diagnosis Cabot found that the percentage of correct clinical diagnoses in various diseases was as follows:

	Percentage of Correct Diagnoses
Diabetes mellitus .....	95
Typhoid .....	92
Aortic regurgitation .....	84
Cancer of colon .....	74
Lobar pneumonia .....	74
Chronic glomerulonephritis .....	74
Cerebral tumor .....	72.8
Tuberculous meningitis .....	72
Gastric cancer .....	72
Mitral stenosis .....	69
Brain hemorrhage .....	67
Septic meningitis .....	64
Aortic stenosis .....	61
Phthisis, active .....	59
Miliary tuberculosis .....	52
Chronic interstitial nephritis .....	50
Thoracic aneurism .....	50

<sup>5</sup> Cabot, Richard C.: "Diagnostic Pitfalls Identified During a Study of 3,000 Autopsies," *Journal American Medical Association*, Dec. 28, 1912, p. 2295.

	Percentage of Correct Diagnoses
Hepatic cirrhosis .....	39
Acute endocarditis .....	39
Peptic ulcer .....	36
Suppurative nephritis .....	35
Renal tuberculosis .....	33.3
Bronchopneumonia .....	33
Vertebral tuberculosis .....	23
Chronic myocarditis .....	22
Hepatic abscess .....	20
Acute pericarditis .....	20
Acute nephritis .....	16

The cases studied were hospital cases under conditions assumed to be favorable to correct diagnosis. It is quite safe to assume that in medical practice at large the percentages of correct diagnoses would be found lower than those found by Cabot.

McLaughlin and Andrews<sup>6</sup> carried on an investigation in Manila into the nature of the diseases from which children were dying. They made post-mortem examinations of children in which certain diseases had been given as the cause of death. The diseases selected were those appearing most frequently in death certificates. The reason for the investigation was to ascertain whether the death certificates showed the real causes of death in children in Manila and if not what the actual causes of death were.

A summary of their findings was as follows:

<i>Assigned causes of death</i>		<i>Causes of death ascertained by autopsy</i>	
Meningitis .....	37	Cholera .....	40
Enteritis .....	22	Beriberi .....	97
Convulsions .....	40	Pneumonia .....	14
Beriberi .....	50	Enterocolitis .....	7
Bronchitis .....	27	Meningitis .....	4
		Nephritis .....	2
		Empyema .....	2
		Acute tonsillitis, pharyngitis, and bronchitis .....	1
		Cerebral hemorrhage .....	1
		Undetermined .....	8
Total .....	176	Total .....	176

In the registration area of the United States very probably the causes given in death certificates of children correspond more nearly to the actual causes of death than they did in Manila. This, however, should be ascertained by careful studies. Mortality statistics cannot be

<sup>6</sup> McLaughlin, Allan J., and Andrews, Vernon L.: "Studies on Infant Mortality," *Philippine Journal of Science*, Vol. V, No. 2, July, 1910, p. 149.

more accurate than the death certificates from which they are compiled.

For a further discussion of the possible scope of the inaccuracies entering into mortality statistics because of the faulty or incorrect statement of cause of death on death certificates the reader is referred to the Twelfth Annual Report of the Bureau of the Census giving mortality statistics for the year 1911, pages 36 to 38.

**Uses of Death Registration.**—Death registration serves a number of highly important purposes. Its functions are legal, economic, and social.

FIG. 152.—BIRTHS AND DEATHS (EXCLUSIVE OF STILLBIRTHS) PER 1,000 POPULATION PER ANNUM  
Registered in Massachusetts, 1871 to 1911.

Death registration is useful in preventing and detecting crime through the restrictions placed upon the disposal of dead bodies. It serves as evidence in the inheritance of property and in the settlement of life insurance contracts and policies. It is only proper that the time, place, and cause of death of each individual should be made a permanent record for both sentimental and legal reasons.

Death registration makes it possible to show by mathematical computations and statistical methods the extent and rate of change in population produced by deaths; the average duration of life; and, to the extent that the certified causes of death have been correctly stated, the relative frequency with which the several causes produce death. Death statistics by comparison with birth statistics give useful information regarding population increase or decrease.

**Death Rates.**—Death rates may be expressed as the ratio of the total number of deaths, taken as a unit, to the population. For example: 1 in 60. The usual method, however, is to express these rates in terms of the number of deaths per 1,000 population, or in some instances per 10,000 or even 100,000, or 1,000,000.

*Crude Death Rates.*—The rate which shows the proportion of all deaths to the total population, and which is usually obtained by dividing the total number of deaths by the total population in thousands, is known as the crude death rate; also as the general or central death rate. To compute the crude death rate the total number of deaths during a year and the mean population for the year (estimated population as of the middle of the year, for the calendar year as of July 1) are taken. To illustrate: In a city having a total of 900 deaths during a calendar year, and an estimated population of 60,000 as of July 1 of the year,

the crude death rate would be  $900 \div \frac{60,000}{1,000} = 15$  and would be expressed as 15 per 1,000 population.

Crude death rates are of value chiefly to show the numerical loss of the population by death. They also serve as a satisfactory basis for the comparison of the death rates of different communities having populations of similar composition as to age and sex. For populations of dissimilar composition they are not suitable as a basis of comparison, for the death rates of women are usually lower than those of men and the death rates of the several age groups vary within wide limits, and the death rate, therefore, depends to a marked degree upon the relative numbers of males and females and the proportion of the population included in the various age groups.

*Death Rates for Short Periods.*—Death rates for short periods (for a week, month, or quarter) are expressed in terms of annual rates; that is, what the annual rate would be provided deaths occurred throughout the year with the same frequency as during the week or month under consideration. Death rates for short periods are likely to have little significance, as quite accidental causes may affect them to a considerable degree. Taken for a number of years, however, they give useful information regarding seasonal variations. If in a city there were 20 deaths during a given week and the mean population of the city for the year was 60,000, then the crude death rate for the week would be

$$20 \times \frac{365}{7} \left( \frac{\text{days in year}}{\text{days in week}} \right) \div \left( \frac{60,000}{1,000} \right) (\text{population of city in thousands}) = 17.38.$$

The mortality for the week would, therefore, be at the rate of 17.38 per 1,000 population per annum.

*Specific Death Rates.*—Special or specific death rates are the rates of specified or limited subgroups of the population. These subgroups may be obtained by dividing the population according to sex, age, race, social condition, occupation, and so on. Specific death rates may be stated as the proportion of the number of deaths per annum in the subgroup per 1,000 of the mean annual number of the population in that subgroup. Sometimes specific death rates are given in terms of 10,000, 100,000, or 1,000,000 of the subgroup population.

Among the most important of the specific rates are those relating to age groups. Their significance is shown by the following statement of rates for the registration States of the United States for the year 1911:

Age Group	Death Rate per 1,000
Under 1 year .....	112.9
1 to 4 years .....	11.8
5 to 9 years .....	3.1
10 to 14 years .....	2.2
15 to 19 years .....	3.6
20 to 24 years .....	5.2
25 to 34 years .....	6.4
35 to 44 years .....	8.9
45 to 54 years .....	13.6
55 to 64 years .....	26.2
65 to 74 years .....	55.2
75 years and over .....	138.9
All ages .....	13.9

Specific race group rates are also important. In the registration area for deaths in 1911, the death rate for the white population was 13.7 and that of the colored 23.7 per 1,000, while the rate of the two groups taken together was 14.2 per 1,000. In 1916 the death rates in the city of Washington were 15 per 1,000 among the white population and 25.4 per 1,000 among the colored; in Baltimore 15.9 for white and 30.7 for colored; in New Orleans 14.3 for white and 30 for colored. For the registration area as a whole the death rates in 1916 were for the white population 13.5 per 1,000 and for the colored 20.5 per 1,000.

In considering the separation of deaths into those of white and colored, one must bear in mind the possibility that in many communities such a separation may amount to a classification according to industrial or economic status, the colored deaths being those in households having the smaller incomes. In this connection one is reminded that investigations into the rate of infant mortality and the relative prevalence of certain diseases, such as tuberculosis, have revealed that the infant mortality rate varied usually with the incomes of the population groups and that the relative prevalence of

tuberculosis seemed to be largely determined by the same factor. It may be that if in the average community deaths could be classified according to economic status—that is, according to the family or household income, a difference in the mortality rates would be obtained approximately as great as that resulting from a white and colored classification.

That a classification of deaths on a basis other than that of color may show differences in mortality rates fully as great as those produced by a white and colored classification is well known.

In New York City (the old city) for the year 1906 the death rate among that part of the population of Irish nativity was 29.26 per 1,000, and among the population of Swedish nativity 11.21 per 1,000, while the death rate of native-born Americans was 18.49. Classified according to the nativity of the parents of the decedents, the death rate among persons whose parents were born in Italy was 36.43 per 1,000; of those whose parents were born in Austria-Hungary, 23.4 per 1,000; and of those whose parents were born in Sweden, 10.97 per 1,000; while of those whose parents were born in the United States the rate was 13.98 per 1,000. The death rate of the colored population throughout the whole city (greater New York) was 27.16. These figures indicate that, in so far as crude death rates are concerned, other groups of the population may have, and in New York City did have, higher rates than the colored population.

The death rate differs also in the two sexes. It is higher for males than for females.

*Standardized Death Rates.*—Due to the wide variation in the death rates at different ages it is impossible satisfactorily to compare the crude death rates of populations differing in compositions as regards the relative number of individuals in the several age groups. The International Statistical Institute recommended (1895) that to facilitate the comparison of death rates the population of Sweden as it existed in 1890 be used as a standard population for the statement of rates. Rates expressed in terms of standard population are known as standardized or corrected rates. The method is as follows: Take the population for which it is desired to state the standardized death rate and ascertain the specific death rates of its several age groups. Now take the corresponding age groups in 1,000,000 of the standard population and compute the number of deaths that would have occurred in each age group at the specific death rate found to exist in the population for which the standard death rate is being computed; add the number of deaths which it is thus found would have occurred in the age groups of the standard population. This gives the standardized rate per 1,000,000. The standardized rate per 1,000 is obtained by moving the decimal point three places to the left.

The standardized death rate is the rate which would have occurred in the standard population if the death rates in its several age groups had been the same as those of the corresponding age groups of the population under consideration.

The registrar general of births, marriages, and deaths of England and Wales has for some years taken for a standard the population composition of England and Wales as shown by the 1901 census. The population of Sweden of 1890 was divided without distinction of sex into the five age groups: Under 12 months of age, over 12 months and under 20 years, 20 to 39 years of age inclusive, 40 to 59 years of age inclusive, and 60 years of age and over. The population of England and Wales is classified separately by sexes in quinquennial age groups and furnishes a much more delicate and exact standard for measurement. The use of the Swedish population standardizes for age; the use of the English standardizes for both age and sex.

**Factors Affecting Death Rates.**—Death rates are affected not only by the statistical methods used in their preparation and by the age, sex, and race composition of the population, the social, marital, and economic status of the people, the nature and conditions of employment and the adaptability of a people to their environment, but also in limited areas by a number of other factors, such as the location of hospitals and institutions.

*Nonresidents; Hospitals and Institutions.*—Frequently a hospital or other institution will be located in one community while its patients or inmates will come largely from other places. The extent to which this is true depends upon the nature or reputation of the hospital or institution. The result may be that the local death rate will be affected to an appreciable extent by deaths of nonresidents in such institutions. In England and Wales an attempt has been made during recent years to overcome this difficulty by the allocation of all deaths in so far as possible to the locality of usual residence. In compiling deaths for a registration district or area for the purpose of showing death rates, erroneous results will be obtained if the deaths of nonresidents are excluded and no additions made for the deaths of residents which are continually occurring and being registered elsewhere.

In the absence of a dependable means of including the deaths of residents occurring in other districts it is, unless under most exceptional circumstances, unsafe to exclude the deaths of nonresidents.

For the public health purposes of mortality statistics nonresident deaths might be considered as those of persons who had been already affected with their fatal illnesses at the time they had come to the locality and who had not developed or contracted the illnesses in the locality.

*Migration.*—Migration affects death rates by changing the age, sex, or race composition of the population. Migrants are likely to con-

sist more largely of males than of females, of young adults than of the extremes of life. The effect of migration depends upon whether the balance is one of emigration or immigration and the nature of the migrants lost or gained.

*Birth Rate.*—Ignoring the question of migration, a population increases because of the excess of births over deaths, natural increase. In a stationary population the birth rate equals the death rate. As all born must eventually die the birth rate depends for its excess over the death rate upon the ever-increasing number of child-producing elements in the population and the resulting greater numbers in the younger age groups. Other things being equal, a community with a high birth rate will, because of the greater proportion of the population in the younger age groups, have a lower crude death rate than a community with a low birth rate.

*Marital Condition.*—Mortality in certain countries seems to be more dependent on marital conditions than on sex. This is shown by the following table taken from a paper entitled "Some Researches Concerning the Factors of Mortality," by Lucien March (*Journal of the Royal Statistical Society*, London, March, 1912):

*Showing for the period 1886-1895, the number of deaths per 10,000 persons according to their marital status in France, Prussia, and Sweden*

	Males, aged—			Females, aged—		
	20-39	40-59	60 and Over	20-39	40-59	60 and Over
France:						
Married .....	77	153	585	80	121	456
Single .....	103	246	794	78	166	730
Widowed or divorced.....	211	293	1,148	145	198	930
Prussia:						
Married .....	71	175	582	79	128	497
Single .....	84	231	806	59	179	729
Widowed or divorced.....	201	346	1,091	101	172	805
Sweden:						
Married .....	53	114	453	66	96	364
Single .....	83	204	690	61	120	528
Widowed or divorced.....	104	190	856	98	132	698

It will be noted in the following table that there has been a marked fall in the crude death rates throughout the civilized world. A study of the deaths by age groups indicates that in the United States the reduction in death rates has been entirely in the younger age groups and that the rates for ages above 45 or 50 years have not only not diminished but have actually increased. This means that a greater proportion of the population than formerly is living to be 50 years of age. The increased death rates among that part of the population over 50 probably means that those saved from earlier death and carried along

to the age of 50 succumb rather rapidly to the vicissitudes of life. It would seem that this is to be expected.

**The International List of Causes of Death.**—Many persons, even among registrars and statisticians, seem to misunderstand the nature of the International List of Causes of Death. It seems to be frequently thought of as being a nomenclature of diseases. It is important that just what it is shall be thoroughly understood.

In the course of the registration of deaths in a population of any size, the names given to the causes of death as written on the death certificates will aggregate in the total many thousands, depending upon the education and training of the physicians signing the death certificates. Several different terms will be used by different physicians for the same disease or, the same name may be used for several different morbid conditions. For instance, typhoid fever will be variously termed abdominal fever, cerebral typhoid, continued fever, enteric fever, gastro-enteric fever, typho-enteritis. Malarial fever will be variously recorded as bilious intermittent fever, chills and fever, dumb ague, fever and ague, gastric remittent fever, intermittent fever, marsh anemia and sometimes as malaria. On the other hand "continued fever," "rheumatism," "pneumonia," "cancer" and "heart disease" are each used as

the name of many different pathologic conditions and it is impossible to know what is meant by these terms unless the user gives his definition of their meaning as used by him.

And so it is with all the other diseases and conditions causing death. It will be readily understood that it is impossible for the statistician to give the occurrence of death for each of the multitudinous causes which are thus found recorded in death certificates. Statistically, it would be an impossible task and from the standpoint of printing and publication and the futility when published, meaningless and of no value. It is therefore necessary for the statistician to take the death certificates and divide them into a practicable number of groups, under which they can be compiled, and for which tables can be published. Every statistical office has done this. The only alternative would have been to give practically a serial statement of deaths and their assigned causes. But where each statistical office determined for itself the groups of causes of death which it would associate together in one table, or, in other words, the groupings under which it would publish its causes of death, no two statistical groupings were the same, and therefore, no two sets of tables were comparable. If the French statistical office made one grouping and published their tables according to their grouping and the English statistical office made another grouping and published their tables according to that grouping, comparative deductions as relating to the mortality data of the French and English peoples would be impossible.

To overcome this difficulty and make mortality statistics of all countries comparable, it was determined about 1893 to decide upon a statistical grouping of causes of death for purposes of tabulation and publication which would be used by the several countries publishing mortality data. As a result of this we have the International List of Causes of Death. Previous to the revision in 1920, the International List contained 189 titles or groupings under which all returns of death may be tabulated.<sup>7</sup> Each title may figuratively be considered as a basket and the 189 titles as the 189 baskets into one of which the statistician drops each death certificate coming to his office. From the assortment of death certificates thus made statistical tables are published. About half of the 189 numbers or titles of the list include but one disease; the others include groups of diseases or death-producing causes.

It will thus be seen that the International List is by no means a nomenclature, nor is it even a classification, unless it be considered a classification for purposes of statistical publication.

Each people speaking a different language has had to determine for

<sup>7</sup> At the time of writing (February, 1921) the numbers of titles in the revised list had not been decided upon by the conference for revision which had met in Paris in the autumn of 1920.

itself which names given on death certificates as causes of death in their respective languages should be included under each of the 189 titles in the International List. The only part of the International List which can be international is the 189 numbers and the titles in so far as the titles are descriptive. To make a list entirely possible of international use, each title should have a number and a definition of the disease or of the class of diseases to be included under that number. For instance, Title 15, "Plague" would be truly capable of international use only when the definition of what is meant by "Plague" is given.

To illustrate the use of this list and how each country has had to determine which terms given on death certificates, as causes of death in their respective countries, should be considered as falling under the several titles of the International List, the list given below is taken from the Manual issued by the Bureau of the Census. The names for causes of death which, when given on death certificates, are to be compiled as coming under Title 1 of the International List, which Title No. 1 is assumed to include only the morbid condition due to infection with bacillus typhosus, are shown. It is readily understood that many of these terms are not used at times for typhoid fever, and their inclusion under that title causes a percentage of error. However, there seems to be no way to avoid this. It will be readily understood also that these secondary lists of terms under each title could by no means be international except among peoples speaking the same language and following much the same usage as to terms.

The following terms are included by the Bureau of the Census under Title 1 of the International List when given as causes of death on death certificates.

Title 1. Typhoid fever.

Abdominal fever.  
Abdominal typhoid.  
Abdominal typhus.  
Abortive typhoid.  
Ambulant typhoid.  
Cerebral typhoid.  
Cerebral typhus.  
Continued fever.  
Enteric fever.  
Enterica.  
Gastro-enteric fever.  
Hemorrhagic typhoid fever.  
Ileotyphus.  
Intermittent typhoid fever.  
Malignant typhoid fever.  
Mountain fever.

Paratyphoid fever.  
Paratyphus.  
Posttyphoid abscess.  
Rheumatic typhoid fever.  
Typhobilious fever.  
Typho-enteritis.  
Typhogastric fever.  
Typhoid fever.  
Typhoid malaria.  
Typhoid meningitis.  
Typhoid stupor.  
Typhoid ulcer.  
Typhomalaria.  
Typhomalarial fever.  
Typhoperitonitis.  
Typhus (unqualified).  
Typhus abdominalis.

# INFANT MORTALITY

Infant mortality is the mortality of infants under 1 year of age. While the specific death rates for other age groups are given as the ratio of the number of deaths to the number of individuals in the age group as ascertained by census enumeration and estimated for intercensal and postcensal years, it is not practicable to do this for the first year of life. There is extreme difficulty in ascertaining by enumeration the infant population. This is due largely to confusion of the current year of age with the completed year of life. Then too, a census of infants under one year of age would be of value only for the year, in which it was taken.

*Infant mortality—Deaths of children under 1 year of age per 1,000 births (exclusive of stillbirths) in certain countries, 1892, 1911 and 1915 \**

\* Taken from the Annual Reports of the Registrar General of Births, Deaths and Marriages in England and Wales, 1911 and 1915.

† Year 1910.

The commonly accepted method of stating infant mortality is as the ratio of deaths of children under 1 year of age to living births, and is usually expressed as the proportion of deaths during the calendar year to 1,000 living births during the same period. To illustrate: If in a city there were during a year 224 deaths of infants under 1 year of age, and if during the same year there were 2,000 births, the infant mortality rate would be 112 per 1,000 births per annum.

Infant mortality rates might be based upon the number of births during the preceding year or upon the mean of the number of births of the current year and the preceding year. However, the number of births of the current year has been accepted as the basis in Great Britain and many other countries.

Making the estimation of infant mortality depend upon birth registration is at present unfortunate in a way for those interested in the subject as it relates to the United States, owing to deficient birth registration in this country and the impossibility therefore of estimating infant mortality rates, except for certain limited areas. However, there is no other practicable basis for estimation. There are, too, other difficulties to be encountered in the use of incomplete birth registration. In the absence of change in other factors an improving completeness of birth registration would give an apparent decreasing infant mortality rate and might lead to unwarranted deductions. See also page 477.

### LIFE TABLES

In theory life tables represent the duration of life of individuals born at the same time. Given a group of individuals born in any one year and a life table will show the number in the group that will still be alive in each succeeding year as long as any remain. It will also show the number who will have died previous to any given year and the number

FIG. 153.—STATE STATISTICS OF ORIGINAL REGISTRATION.

Chart showing the number of white males and white females in both the rural and urban populations, and of colored (negro) males and colored females in the total population, remaining alive at each age out of 100,000 born alive in the "original registration States."—Based upon the "United States life tables: 1910," published by the Bureau of the Census. Taken from *Public Health Reports*, April 6, 1917.

dying during each year. To observe a group of individuals from the cradle to the grave is under most conditions impracticable, and besides yields information the value of which is largely lost before it is obtained, for conditions affecting longevity may change and the life history of one generation may be quite different from that of the next.

Much of the value of a life table consists in showing current condi-

tions as they affect the longevity of the community or race. For this purpose tables are constructed from the information furnished by an enumeration of the population (census) classified by age and sex and the registration of deaths with the decedents classified also by age and sex. The population age and sex groups give the number and proportion remaining alive at each year of age, the deaths show the number dying at each year of age. For the purpose of getting data which show general conditions prevailing during the period, and of avoiding the errors which might arise by using the death records of a year during which usual mortality conditions prevailed, the death records for a number of consecutive years are usually used.

Given the above data, the expectancy of life or mean after lifetime at a given age is readily obtained. The following table is one prepared under the direction of Dr. William H. Guilfoxy, registrar of records of the New York City department of health, and published in the monthly bulletin of the department for May, 1913. It compares the expectation of life based on the mortality experience of the three years 1909, 1910, and 1911, with that found by the late John S. Billings based upon the experience of 1879, 1889, and 1881:

*Approximate life tables for the city of New York based on mortality returns for the triennials 1879 to 1881 and 1909 to 1911. (Guilfoxy.)*

The Bureau of the Census issued in June, 1916, life tables prepared under the supervision of Professor James W. Glover. The tables relate chiefly to mortality conditions in the area known as the original registration states comprising Maine, New Hampshire, Vermont, Massachu-

setts, Rhode Island, Connecticut, New York, New Jersey, Indiana, Michigan, and the District of Columbia. The chart on page 1276 is based on the material in these tables.

## SECTION XII

### INDUSTRIAL HYGIENE AND DISEASES OF OCCUPATION

Industrial hygiene is one of the most important topics in preventive medicine, as it deals with the health, the welfare, and the human rights of the vast majority of the population. Industrial hygiene is a subject in which the medical, economic, and sociologic aspects are closely interwoven, and it requires a broad grasp and intimate knowledge of the conditions to avoid the dangers and correct the injustices to which work-people are subjected. The questions of industrial hygiene strike at the very root of our social system; they include the relation of capital and labor, and the relation of man to his fellow men. The man of means may, to a large extent, select not only the place, but even the character, of his employment. He can choose his own hours of work and can largely control his environment while at work, so far as it affects his health and comfort; he can purchase fresh air, sunshine, good food, rest, recreation, and other conditions that make for health, longevity, and happiness. The employee must largely accept the conditions as he finds them and is frequently denied many advantages, even necessities. As the power of the employee is limited, he needs the assistance of the state to correct the unreasonable demands which capital has ever exacted of labor. Legislators should champion the rights of work-people, especially in the realm of industrial hygiene. Our country has been negligent in this regard and has fallen far behind England and Continental countries. The situation has received some assistance through organized labor, which has exerted a good influence in limiting the avarice of the employer, in shortening the hours of work, in obtaining a more just share of the profits, in improving sanitary conditions, and in exacting a modicum of human consideration. Thus when the stone masons came to build the Hygienic Laboratory in Washington they refused to work until a proper shelter and other reasonable conveniences were provided, as required by their labor union.

Modern conditions have brought entirely new problems into industrial hygiene. These have come about largely through the development of new industries and the invention of new processes, through improved and changed methods of transportation, and through specialization and crowding in cities and work places, through artificial light, through changing relations between capital and labor, and the intensive and un-

relenting pressure of the times. Some of the conditions which oppress the workmen are brought about by the greed of capital and disregard of the human machine, but indifference, carelessness, and ignorance of the workman himself are responsible for many avoidable accidents and preventable maladies. In Eastman's study of work accidents in Pittsburgh it appeared that, out of 410 fatal accidents, the victim or his fellow workers were responsible in 188 cases and the employer in 147 cases. Despite the improvements in labor-saving devices the human machine will ever remain the most vital and indispensable machine in the production of wealth—at the same time it is the most delicate and sensitive machine. Both from the standpoint of humanity and the standpoint of economy the human machine deserves greater care and consideration than any other mechanism engaged in production.

The diseases of occupation are especial dangers to health incident to certain industries, such as liability to lead poisoning in the manufacture of white lead; of phossy jaw in the manufacture of matches made with white phosphorus; of caisson disease in divers and those who work in compressed air; special affections are sometimes caused by exposure to high temperatures; there are extra hazards to life and limb in railroading, mining, and among those who work with explosives; there is a particular danger to those who are compelled to work in a dusty atmosphere, more so if the dust is of an irritating or poisonous nature; and there is danger to those who are compelled to breathe poisonous fumes such as carbon monoxid, hydrogen sulphid or mercury. Most industrial poisons are due to gases, vapors and dust. Further, there are many forms of neuroses due to certain kinds of work; and finally infections such as anthrax, glanders, and hookworm disease. These special instances represent the true diseases of occupation.

*Industrial hygiene*, on the other hand, includes many influences, not specifically inherent in industry, to which the workman is often subjected which seriously influence health; such as poor ventilation, lack of cleanliness, overcrowding, excessive hours, improper light, fatigue, and a hundred and one conditions which affect the health and the efficiency of the workman. The prevention of the communicable infections among work people is based upon the same principles and practice as for the civilian population. Work should be ennobling, and anything which tends to degrade it is morally wrong.

The statistics of morbidity and mortality in relation to diseases of occupation need careful scrutiny, especially when used for comparison. The factors which enter into such statistics are so numerous and the conditions so variable that misleading conclusions are common. The workmen come and go, they vary very much in physical vigor to start with, are of all ages, both sexes, many nationalities, and are greatly influenced by home conditions and by the character of their recreation. Some

industries, while not in themselves particularly hazardous, are rendered so through intemperance or dissipation. On the other hand, there is a relation between low wages and a high morbidity rate in a given industry. Low wages mean poor housing, insufficient clothing, poor food, unhealthful recreation, increased temptation to alcoholism, and an undue proportion of youthful workers, of women, and of men more or less handicapped by poor physique or bad habits. The statistician therefore must be careful to take all factors into account that bear upon the

FIG. 154.—SYSTEM OF HOODS AND VENTILATORS TO CARRY OFF THE FUMES FROM THE FURNACES IN A FOUNDRY. (Mass. State Board of Health.)

subject. Some industries are blamed for conditions affecting health that may be due to the insanitary home conditions and bad habits of the individual.

In recording the nature of a man's work it is not sufficient simply to state that he is a laborer, mechanic, machinist, mill operator, and the like. Such information is frequently of no more value to the student of the diseases of occupation than the name of the person himself. A "machinist" may set hair springs in watches or repair automobiles. If the person is a blacksmith or works with heavy metals it is plain that he works under a severe physical strain. If he is a sailor upon a sailing ship we know that he is exposed to rough weather and unusually severe conditions, whereas if he is a sailor upon a modern passenger steamship

the conditions of his work may be no more severe than those of the janitors and charmen in a large office building. If he is in finance we may be sure that he is subject to severe nervous strain. It is therefore not sufficient simply to give the name of the trade, but detailed inquiry should be made into the precise nature of the individual's work and the particular conditions under which he works.<sup>1</sup>

Most of the investigation of industrial poisons in the United States has been made within very recent years, and the field has not yet been nearly covered. Careful studies have been made of two poisons, white phosphorus<sup>2</sup> and manganese,<sup>3</sup> most of the more important lead industries have been studied,<sup>4</sup> and there are some excellent surveys of the brass industry<sup>5</sup> and of the various occupations in which mercury<sup>6</sup> or its compounds are used.<sup>7</sup> There is urgent need for more study of several poisons which are quite extensively employed in our industries, such as carbon monoxid; white arsenic and arseniuretted hydrogen gas; vanadium; selenium; carbon disulphid; sulphurated hydrogen; benzene; toluene, and their many derivatives, of which anilin is the most important; methyl alcohol; amyl acetate; carbon tetrachlorid; acetylene tetrachlorid, or tetrachlorethane; aldehyds, acetones and cyanogen.

Conditions in American industry vary much more widely in different plants than they do in the older countries, and while our best factories are equal to the best in Europe, or occasionally are even better, the worst fall below the standard required by law in Europe. There is on the whole, in America, more recklessness in the handling of trade poisons and the result is shown in all the statistics of industrial poisoning that have been collected. Thus, in the making of storage batteries, a dangerous lead trade, the rate of poisoning in the five largest

<sup>1</sup>The Massachusetts legislature of 1904 took the first step in this country to obtain definite scientific data on the subject of the occupational diseases. The State Board of Health of Massachusetts made an investigation into the sanitary condition of factories, workshops, and mercantile establishments, and published its first report on the subject in 1907. Since then several States have taken up the subject, also the U. S. Dept. of Labor and the Amer. Assn. for Labor Legislation. The Hospital for Industrial Diseases at Milan, opened March, 1910, is the only institution in the world devoted specifically to the investigation and care of such diseases. The first American Congress on Industrial Diseases met in June, 1910.

The earliest successful attempts in England to enforce sanitation and to secure healthy conditions of work were introduced by the Act of 1833 involving the appointment of paid factory inspectors, who antedated medical officers of health and sanitary inspectors.

factories in the United States in 1914 was 17.9 per cent., while Great Britain's rate for 1912 was 2 per cent., and the largest factory in Germany had only 0.97 per cent.

Andrews estimates that in the United States 30,000 wage earners are killed by industrial accidents every year, and that at least 500,000 more are seriously injured. A memorial on industrial injuries prepared by a committee of inspectors, appointed by the President of the Association for Labor Legislation, states that there are probably not less than 13,000,000 cases of sickness each year among those engaged in industrial employments. The money lost each year (for those who find dollars more expressive than lives) is conservatively calculated at nearly three-fourths of a billion dollars. At least one-fourth of this painful incapacity for work and consequent economic loss can be prevented.

Good industrial conditions mean money in the pockets of the employer. Thus, Elliot Washburn reports the instance of twenty-eight emery grinders in Massachusetts working in a badly lighted and poorly ventilated basement, who increased their efficiency 30 per cent. on being transferred to a well lighted and ventilated workroom.

The reporting of occupational diseases is a public health measure, and of first importance for their control.

An industry may be a nuisance or disturbance to the community as well as to those engaged in its various processes. Thus, the noise of a tack factory or boiler shop, the smells from glue or fertilizing factories, or the fumes from smelting or chemical works, or the smoke from chimneys or locomotives, wastes from tanneries, paper mills, and mines do not come directly in the chapter of industrial hygiene, however closely related.

## **SOME FUNDAMENTAL CONSIDERATIONS IN PREVENTION**

In order to improve the hygienic conditions under which people work, and in order to prevent the diseases of occupation, five fundamental conditions are essential: (1) investigators; (2) laws; (3) factory inspection; (4) penalties; (5) education. It is self-evident that before anything can be accomplished a careful study must be made of the facts. These investigations must include not only scientific studies, but also economic and sociological factors. Every large industrial center should have a clinic for the study and care of industrial diseases. The subject should be included in the curriculum of medical schools. Suitable laws are necessary, for it has been found in practice that the conditions cannot be corrected by an appeal to voluntary reform. To be effective the laws must provide ample ways and means for their energetic enforcement. A systematic factory inspection is necessary in order not only

to protect work people against the preventable diseases of occupation and to correct sanitary defects, but also to enforce the laws concerning hours of occupation, child labor laws, and related subjects. These laws have little force unless they provide a penalty against both the employer and the employees. Either party to the contract should be held legally responsible in case of violation. Finally, education directed to the employer, the employee, and also to the public at large is necessary to obtain the laws and maintain the standards.

**Hours of Work.**—No general rule can be laid down for the hours of work, which may vary with the character of the employment. Thus the hours of active work are limited by a smith or glass-blower, a worker in a caisson or mine, a locomotive engineer, and other occupations necessitating great muscular effort or intensive concentration, or exposure to unnatural conditions. Formerly men worked at the quieter occupations all the time not given to sleep; now the day is better divided into eight hours of work, eight hours of "re-creation," and eight hours of sleep. Hygienically, it is important to have one full day's rest each week. It cannot be maintained from the medical side that working longer than eight hours a day is harmful to health, but it is held that no employer has the right to utilize the greater part of a man's day and thus deprive him of the leisure to which he, as a human being, is entitled. Since his whole nature has to be developed, time must be given for the intellectual, moral, and physical welfare of man, which cannot take place if the hours of employment are too long, the work too hard, or of a grinding nature. The hours of work depend somewhat upon the physical exertion required and also upon the nervous tension. The Saturday half holidays, especially during the heated term; a vacation period, and a tendency to increase the number of holidays are all signs of social improvement which make for health and happiness.

**Fatigue.**—Economic engineers find that it pays to give employees a rest at stated intervals and to guard the conditions surrounding workers, so that they are neither molested nor interrupted, that the light and other factors are agreeable, and the sanitary surroundings good. Work and rest must be judiciously alternated. Efficiency ceases when fatigue begins. The danger to the workman himself, as well as to others, is now recognized from a tired brain, tired nerves, and tired muscles. Accidents are especially prone to happen to workmen who are tired. Thus most accidents in factories happen as the day wears on. The effect of fatigue on the occurrence of accidents is graphically shown by French and Belgian statistics. The number of accidents increases progressively during the morning hours, drops after the noon intermission, and then rises from hour to hour until the end of the working day, affording a practical illustration of Helmholtz's experiment in attention fatigue. Fatigue is not only dangerous to the workman himself, but sometimes

to others; thus the overwrought and tired-out train dispatcher may send trains into collision. Further, fatigue of certain nerves and muscles may result in definite symptoms such as writers' cramp, or more general manifestations such as neurasthenia or nervous prostration. Typewriters, telegraph operators, and others suffer from these occupational neuroses.

Spaeth<sup>8</sup> draws attention to the difference between normal fatigue which is harmless and cumulative fatigue which is dangerous and may be associated with serious nervous disorders—industrial psychoneuroses. The one merges into the other, and therefore the reduction of normal fatigue is the first logical step in a prophylactic attack.

Fatigue is also believed to predispose to certain infections, such as cerebrospinal fever and perhaps pneumonia and other respiratory diseases. The experience of the World War clearly showed that all attempts to make a soldier too rapidly, through fatiguing drills, invite disaster.

Next to fatigue, nervous tension and worry are very wearing, and when combined become especially harmful. Diabetes prevails among engine drivers to a considerable extent. Worry, hurry, and a high nervous tension are recognized as a frequently predisposing cause of ill health or breakdown in all walks of life, including the so-called higher professions.

*The "Monday Effect."*—It has long been known that workers are less efficient on Monday and following holidays than on other days of the week. Efficiency experts know that the smallest output of the week occurs on Monday.

The usual explanation of this has been misuse of the week-end leisure and of the week's wages—as excessive eating, excessive drinking, late nights and insufficient sleep, or dissipation of other kinds. But it is now apparent that these are not the real reasons for inefficiency following a rest. A. F. Stanley Kent<sup>9</sup> has shown that the week-end rest affects both fatigue-production and recovery from fatigue on the one hand, and output on the other. There is not only a feeling of lassitude and a disinclination to work, but also an actual diminished efficiency. In other words, upon return to work after a rest, the workman is out of practice, has forgotten, and finds a certain amount of loss of coördination rather than actual fatigue. He must relearn before the accustomed efficiency can be regained. This same phenomenon is observed in the familiar behavior of a muscle which after a rest shows a progressive improvement as a result of activity—the contractions increasing in a "stair-case" effect. Workers in nitroglycerin, naphtha and ether always feel the effects of these substances more on Monday or following a holiday; in fact, workers in nitroglycerin carry some of

<sup>8</sup>*Journ. Industrial Hygiene*, I, No. 9, Jan., 1920.

<sup>9</sup>*Journ. of Physiology*, 1915-16, LV.

this substance in their hat band if they go on a week's vacation in order to avoid the nitroglycerin headache upon reëxposure.

**Minors.**—The first factory act in this country was passed by the State of New York in 1886. By this act no child under 13 years of age was allowed to work in factories. Since then, the minimum has been raised to 14 in forty-five states, and in seven of these the limit is higher than 14 years.

A national minimum age of 14 years for industrial employment has in effect been established by the passage in 1918 of a measure providing for a tax<sup>10</sup> of ten per cent. on the entire net profits for the taxable year, of any mill, tannery, factory, or manufacturing establishment in which children under 14 have been employed or permitted to work. The same act prohibits the employment of children under 16 in any mine or quarry, a provision previously established by statute in nineteen states, while Texas places it at 17 years, and Arizona and Wisconsin at 18 years.

The injustice to the child and the consequence upon its health and development of subjecting it to the monotony and grind of factory life are too evident to need emphasis. Recently it has been claimed that in certain districts, as, for example, the mill district of our southland, the children are better off in a good textile mill of modern construction than they are living under the insanitary conditions of their homes. It would be just as logical to state that they would improve in health if removed to a sanitary prison or almshouse. The child of today is the citizen of tomorrow and his health and development are the most important assets of the state.

In Massachusetts minors under 18 years of age are excluded from the following occupations:

1. Processes involving exposure to poisonous dusts or substances, such as the manufacture of lead, lead pipe, plumbers' supplies; electrotyping, handling white lead or lead monoxid (litharge) in rubber factories; lead-paint grinding; lead working in the manufacture of storage batteries; file cutting by hand; typesetting; cleaning or handling of type in printing offices; glazing in pottery establishments.

2. Processes involving exposure to irritating dusts, as graphite in the manufacture of stove polish; bronzing in lithographing business; cutlery grinding and other grinding; polishing on emery or buffing wheels; cutting, grinding and preparing pearl shell; tale dusting in rubber works; sorting, cutting or grinding rags; filing grooves in steel rolls by hand.

3. Processes involving exposure to poisonous gases and fumes, as exposure to naphtha in the manufacture of rubber goods, in japanned

<sup>10</sup> The constitutionality of this tax (Title XII of Revenue Act of 1918) has not yet been passed upon by the Supreme Court.

or patent leather; exposure to fumes or gases from lead processes; and the spraying of amyl acetate on pictures.

4. Processes involving exposure to irritating gases and fumes, such as gassing in textile factories; singeing in print works; bleaching and dyeing works, and dipping metal in acid solutions.

5. Processes involving exposure to extremes of heat and other conditions which promote susceptibility to disease, as melting or annealing glass.

In respect to age limit, the American laws compare very favorably with those of European countries, but in other respects they lag behind. Thus, while Great Britain, Denmark, France, Norway, Sweden and Switzerland have established 18 as the minimum age for night work, only three American states place it so high, and the Federal taxation law fixes it at 16 years. The Children's Bureau Conference, called in 1919 to set standards for employment of children in industry, advised the prohibition of night work under 21 years, because of the physical and moral dangers which night work for the young entails. American laws also fail to protect children adequately against the unhealthy processes in industry. Pennsylvania alone debarb young persons under 21 years from certain lead processes, while a limit of 18 years is prescribed in Maryland, Massachusetts, New Jersey, Ohio and Wisconsin. This means that in 42 states boys and girls of 14 years may be employed in work exposing them to lead, mercury, arsenic, benzene, carbon disulphid, carbon monoxid, etc. All of the European countries recognize the dangerous nature of such work for immature persons of both sexes, and have placed it under legislative control.

**Women.**—The protection of women in American industries also falls below the standard of other great industrial countries. Women are physiologically not capable of doing the same work as men, especially during the period of maternity. Further, several days each month women are more or less incapacitated for most kinds of work on account of menstruation. Pregnant women should not work for several weeks before labor, and after labor not until the uterus has undergone involution, which is a matter of another month. It is in regard to the prohibition of work immediately before and immediately after childbirth, the prohibition of night work, and of employment in poisonous processes, that the laws of many of our states are inadequate. Connecticut, Massachusetts, New York and Vermont have passed legislation to cover the first point. Only nine states prohibit the night work of women, although so long ago as 1906 all the countries of Europe except Norway, Denmark, Roumania and Servia signed the "Berne International Convention" prohibiting it. Only Pennsylvania and New Jersey exclude women from the dangerous lead trades, and New York and Ohio have a curious law prohibiting women from working with emery and polishing powders.

Mr. Brandeis successfully defended the constitutionality of the ten-hour law for women in Oregon. The brief submitted by this eminent jurist in a similar action before the Illinois Supreme Court<sup>11</sup> should be read by those interested in this subject. The primary object of this brief is to show that the demands of public health require legal restrictions in the work of women because of the peculiar importance to the community of the health of mothers. The effect of overwork on the different organs is reviewed, also the effect of night work, of prolonged standing on the feet, of foot-power machinery, and of the speeding up required by the "piece-work system." The general literature upon fatigue and overwork is reviewed.

The effect of overwork upon fecundity and upon infant mortality is impressive. Broggi states that of 172,365 Italian women between the ages of fifteen and fifty-four years who were employed in industrial occupations the average child-bearing coefficient was only about one-third of the general fertility of Italian women.

It is now a well-established fact that infant mortality is shockingly high among the babies of women who work in factories and mills. It has been shown in Germany and England that infant mortality increases progressively according to the increase in the proportion of women obliged to work outside of their homes, and this is true even if the mother's work results in higher standards of comfort in the home. The two classical demonstrations of this rule are the great Lancashire cotton famine and the Siege of Paris, during both of which crises there were loss of employment and great privation. In spite of the starvation and the increased general death rate, the infants' death rate fell in Paris actually to 40 per cent. simply because the women, being out of work, were obliged themselves to nurse and care for their children. The infant mortality in industrial centers such as Fall River, Lowell, and Lawrence, in Massachusetts, which are mill towns, is twice as high as similar towns without many factories and better economic standards.

It is plainly the duty of the nation not only to restrict the hours of work of women, but also to prohibit their employment in certain industries known to be particularly hazardous to them. The evidence presented by the British, especially by Oliver,<sup>12</sup> on industrial lead poisoning shows clearly the greater susceptibility of women to this poison, the severity of the form it takes in women, and the disastrous effect of maternal plumbism on the offspring (see page 1296). Although we have no statistics to prove it, there is every reason to believe that the same thing is true of other poisons used in industry. Protection should also be given to women against less striking evils in industry.

<sup>11</sup> Brandeis, Louis D., assisted by Goldmark, Josephine: *Brief and Argument for Appellants*. In the Supreme Court of the State of Illinois, December term, 1909.

<sup>12</sup> *Dangerous Trades*. London, 1902, p. 296.

Saleswomen should be provided with seats in shops so as to avoid the ill effects of prolonged standing, they should have one or two days each month for rest during the menstrual period, and should be protected against undue strain and fatigue. While women's work may be regulated in the industries and the hours of employment may be limited by law, there can be no law to regulate women's work in the household which is "never done." Men have still to learn the lesson that nervous breakdown and the results of fatigue are as harmful in women who overwork in the home as in those who work in shops and factories. The long hours and confining work of house servants sometimes lead to anemia and other troubles. Cooks are exposed to the effects of excessive heat and to sudden changes of temperature. Domestic "servants" as a class supply a large contingent of patients in hospitals and out-clinics. The long hours and insufficient sleeping accommodations, as well as the nature of the work, lead to ill health which may in part account for the disinclination of women to accept this kind of service.

**Factory Inspection.**—There is no longer doubt but that factory inspection is necessary as a protection to the workman. An efficient system requires a good comprehensive basic law and a capable corps of inspectors. The inspectors should be thoroughly familiar with the law and with the processes of manufacture and also with the problems of preventive medicine. Factory inspectors should be capable of making recommendations outside of the strict regulations under which they operate so as to improve conditions and meet the needs of an ever-changing situation. Factory inspection really falls into two categories, one of which deals mainly with the medical side and the other with the legal and economic side. Both inspectors should take into account the social and humanitarian side. Some of the factors which should engage the attention of a factory inspector are: ventilation, dust, gases, vapors, odors, temperature, moisture, light, cleanliness, over-crowding, excessive heat, dampness, drinking-water, children, women, washing facilities, water-closets, cloakrooms, receptacles for expectoration, defective sanitary arrangements, hours of work and rest, the age of the employees, their physical condition, etc. Hanson points out that medical men, through their training and attitude, make the best factory inspectors, for they alone are in a position to make the best use of facts, and learn something of the sanitary conditions of premises where men and women work, to study the possible injurious effects of certain processes, to inspect devices designed to protect the employees against injury or against dangerous fumes and dust, and to judge the effects on the health of operatives of such substances, as well as to detect the symptoms of certain poisons incident to such occupations, to detect and protect the employees and others from infectious diseases, to make physical examinations of minors, and to collect and make proper use of all facts and data, including morbidity

and mortality statistics, pertaining to occupational hygiene. The medical inspector is also able to correlate the injurious influences in the factory, in the home, and in the habits of the individual.

**Preventable Accidents.**—The most obvious and striking of the preventable accidents occur on railroads, in mines, and in factories. About 10,000 persons are killed and 100,000 more or less seriously injured on the railroads of the United States every year. Some 3,000 fatal accidents occur annually in the course of mining operations, and probably 5,000 deaths result from accidents, in the operation of machinery in factory and workshop. Much of this is preventable, in fact, prevented in other countries. Winslow points out that fatalities are four times as common among our railroad employees as among those of England, and other accidents seven times as frequent. Coal mining was nearly as fatal in Belgium between 1830 and 1840 as it is in the United States to-day, but the Belgians have cut their death rate down to less than one-third of what it was.

Some special injuries incident to work are: spinal curvature from faulty posture; flat feet or varicose veins from prolonged standing, as in nurses and footmen; injuries to the eyes from metal splinters or stone fragments; impairment of vision from improper lighting, or eye strain, as in garment workers and gun pointers, or miners' nystagmus; injuries to the ears, as rupture of the tympanum from air pressure in caissons; labyrinthine disease leading to deafness in boiler-makers and gunners. Injuries to the skin are commonly caused by violence, but may result from excessive moisture, as hydrocystoma of laundresses; chilblains of cold storage workers; and ulcers caused by X-ray or radium—most of which are readily preventable.

A system of workmen's compensation, by which the victim of industrial accidents, except when caused by his own neglect, is entitled by right, and without legal proceedings, to a proper money equivalent for the injury received, is simple justice which has been long delayed in this country. Workmen's compensation laws have been in successful operation in all the principal European countries. Many of our larger corporations voluntarily and automatically compensate employees in case of accidents.

Workmen's compensation laws, the first of which was enacted in 1911, are now enforced in 42 states and the Federal Government provides such protection for its own million civilian employees. The compensation provided runs from 50 per cent. of the wages to 66  $\frac{2}{3}$  per cent., and in case of death, the plan generally adopted is to give the widow 35 per cent. of her deceased husband's wages with 10 per cent. in addition for each child, the total never to exceed 66  $\frac{2}{3}$  per cent.<sup>13</sup>

A compensation law should cover all industries and not alone those

<sup>13</sup> American Asso. for Labor Legislation, 131 E. 23rd Street, New York City.

that are hazardous; it should include disability from occupational poisons as well as from accidents: the payment should be adequate and certain. A good compensation law is one of the best preventive measures, for it has been found that employers soon discover it pays to safeguard the workmen.

In the case of *Vennen vs. New Dells Lumber Company*, 154 N. W. Rep. 640 (Oct. 26, 1915), the Supreme Court of Wisconsin decided that the death of an employee caused by typhoid fever, which was contracted by drinking impure water furnished by the employer, was the result of an "accident" under the terms of the Workmen's Compensation Law, and that the employer was liable.

**Sedentary Occupations.**—Sedentary occupations in themselves may lead to harm, especially in the cases of those who bend forward while at work, causing contraction of the chest and pressure upon vital organs which interferes with important physiological functions. The circulation is impeded, respirations are shallow, the utilization of food is diminished and the appetite fails, constipation and hemorrhoids are common, and there is a predisposition to common colds and diseases of the lungs.

*Health insurance*, or "sickness insurance," is a method by which the economic loss caused by sickness is distributed among a group of persons. The distribution is effected by the payment of periodic premiums on the part of members of the group. In this way the cost of sickness arising from the stoppage of income, from fees of doctors, nurses and hospitals, from expenditures for medicines and the like, does not come as a sudden financial burden to the insured individual. This kind of insurance is now provided in the United States by many commercial companies and by thousands of fraternal orders and benefit associations of a wide variety of types, and is taken advantage of by a large proportion of those who are thrifty enough and financially able to pay the premiums. In the principal European countries sickness insurance of wage earners has been made a governmental function, but with certain fundamental differences from that form of sickness insurance which exists in this country. Among these differences are its extension to all wage earners upon a compulsory basis, the addition of medical and hospital service and certain other benefits to the cash payments to the sick, and the distribution of the cost of insurance not only among the insured, but also among the two other groups—employers and the public—who are considered responsible to some degree for the conditions which affect the health of the insured. The proposals for governmental health insurance in the United States not only adopt the principles just mentioned, but include additional features. Among these are adequate medical service for the insured, and definite provisions for rendering the health insurance system an aid to disease

prevention. It has been proposed that the preventive force of governmental health insurance should not be limited to the financial relief during sickness, to the medical services afforded, and to the possible economic incentive to reduce sickness, but that it should be greatly increased by linking the health insurance system to the existing public health agencies. In this sense, "sickness" insurance, it is believed, would become a real health measure. It would not be merely a variety of commercial or mutual insurance, or another type of public relief, but a practical method of improving and extending the present facilities for the prevention of disease.

## DISEASES OF OCCUPATION

**Classification of the Occupational Diseases.**—Oliver divides the occupational diseases into five general classes:

1. Diseases due to gases, vapors, and high temperatures.
2. Diseases due to conditions of atmospheric pressure.
3. Diseases due to metallic poisons, dusts, and fumes.
4. Diseases due to organic or inorganic dust and heated atmospheres.
5. Diseases due to fatigue.

The principal health risks in industry, as far as we know them, may be conveniently classified according to their nature as follows:

1. Dusts, fumes, gases, vapors, and acids (poisonous and non-poisonous).
2. Harmful bacteria and microörganisms.
3. Compressed or rarefied atmospheres.
4. Improper lighting.
5. Extremes of temperature.
6. Excessive strain.

Many other classifications have been attempted, but it is evident that no general system can be entirely satisfactory. Each occupation requires individual study and separate consideration. In many occupations a combination of varying factors, such as dust fumes, poisons, fatigue, etc., operate coincidently. In the following pages only the well-known and better studied diseases of occupation and the conditions which render them hazardous, as well as methods of prevention, are considered. The number of occupational diseases is rapidly growing as the subject is receiving more careful attention. Thus recently it has been shown that workers with heated tallow and other animal grease are subject to gastrointestinal disturbances, apparently due to the volatile fatty acids that are given off and that the workers ingest and inhale. A large number

of cases of poisoning by fumes of arseniuretted hydrogen have been reported in recent years, the gas being accidentally evolved when a metal such as zinc or iron containing arsenic as an impurity is brought in contact with a heavy acid. Skin diseases are caused by many of the coal tar derivatives, by some of the petroleum distillates, and are also frequently found among workers in the following trades: galvanizing, cutters of glass and pearl shell, workers with tar, paraffin, cement, dyes, printer's ink, and polishers.

A comprehensive list of substances that injure working people would be long and impressive. It includes acids and alkalies, petroleum, gasoline, naphtha, paraffin, coal tar and its derivatives such as benzene, anilin, phenol, nitranilins and nitrophenols, toluene and trinitrotoluene (TNT), carbon disulphid, sulphurated hydrogen, the alcohols, especially methyl alcohol, chlorid of lime, the chromates, cyanogen, turpentine, the oxids of nitrogen, amyl acetate, formaldehyd and very many others.

### LEAD

Lead poisoning is one of the most frequent, most serious, and most insidious of all the occupational intoxicants. If a pound of lead drops on a workman's head the catastrophe is more obvious than if minute quantities of lead are taken into the system day by day, but the poisoning may be as fatal as the accident. "Epidemics" of lead poisoning sometimes occur from the drinking water, from beer and from other unusual sources.

Lead is a typical cumulative poison. A large amount may be taken at one time without noticeable effect, but small quantities ingested daily are absorbed, stored in the body, resulting in chronic poisoning and even death. Lead is excreted both by the kidneys and the liver, and also the skin. It probably does not appear in the urine except with albumin, that is, lead can only pass a damaged kidney. The lead excreted by the liver passes into the intestines with the bile and may be found in the feces. The elimination of the lead, however, is slow and uncertain. As much as one ounce of the acetate of lead has been taken at one time without injury. Older physicians frequently prescribed the acetate of lead as an astringent in doses of 10, 20, or 30 grains. The same amount of lead distributed in minute doses and taken daily, would in all likelihood, result in serious poisoning. The reason for this is that when one large dose is taken only a small quantity is absorbed; the rest is swept through the intestines, but when small quantities are taken at frequent intervals practically all is absorbed and the metal accumulates in the tissues, poisoning especially the delicate nervous structures.

The susceptibility to lead poisoning varies greatly. Of a number of persons exposed to the same conditions some are fatally poisoned, others

suffer with mild plumbism, and still others escape entirely. Young persons are much more susceptible than old. Young adults suffer most. Women are more susceptible than men. Recognizing this fact, in 1898 England abolished female labor in the dangerous processes of white lead manufacture. The reasons for this varying susceptibility are only partly understood. Hyperacidity of the gastric juice is a predisposing factor, because the lead in such persons is readily converted to the soluble chlorid in the stomach. Personal cleanliness is another important factor, and workers in lead who do not give scrupulous attention to cleanliness of person and clothing suffer most. Persons who are not particularly careful about cleaning their hands before eating, or who frequently carry their fingers to their mouth and nose, run especial risks. Oliver has shown by experiments on animals that alcohol precipitates attacks of plumbism, a fact which, in the human subject, clinical experience has again and again confirmed. There is not the least doubt that alcoholic intemperance predisposes to lead poisoning.

Practically all forms of lead are poisonous, even the metal itself. The basic carbonate and the suboxid are the most dangerous; the higher oxids, litharge and red lead, come next. The sulphate and chromate are less soluble in human gastric juice and the sulphid is the least soluble. The water-soluble compounds, the acetate, chlorid and nitrate, are unimportant in industry and do not often give rise to any trouble.

In the majority of cases of lead poisoning in the industries the lead comes through the air to the victim as dust, sometimes as fumes. Preventive measures must, therefore, be directed toward keeping the air about the workmen free from lead. A lead trade is dangerous in proportion to its dustiness. Lead is usually taken into the system through the digestive tract, although absorption from the respiratory tract and even through the skin may occur. For many years it was a disputed point whether the lead entered through the skin or the intestinal tract, but it is now conceded that the intestinal mucosa, also that of the mouth, is the usual portal of entry. Much of the lead dust that is a source of lead poisoning is, in fact, swallowed. Lead is also carried to the mouth by the fingers, pipes, chewing tobacco, and in a great variety of other ways.

The water-soluble salts of lead such as acetate, chlorid, and nitrate may be absorbed through the skin, but this is slow and requires long exposure. It is possible that the non-soluble salts may be changed by contact with the fatty acids on the skin into soluble compounds. Lead poisoning may be caused by absorption through the skin from cosmetics containing lead. Edsall thinks skin absorption relatively unimportant. In this he is in accord with Weyl, Legge, Oliver, and Sommerfeld.

The classical symptoms of lead poisoning are a bluish black line or, rather, collection of tiny spots (sulphid of lead) along the margin of

the gums especially of the lower incisors; loss of appetite, headache, constipation, colic, "rheumatic" pains in the joints and muscles, more particularly in the back; sleeplessness and various vague nervous disturbances. Among the earliest manifestations of lead poisoning is the pallor of the skin, out of proportion to the anemia as determined by the redness of hemoglobin and the number of red blood cells. Lead can often be found in the urine, almost always in the feces, and examination

FIG. 155.—RED OXID OF LEAD AND LITHARGE BEING MIXED IN THE MANUFACTURE OF STORAGE BATTERIES.

The workman is wearing a respirator, but should also protect himself with long-wristed gloves.

of the red blood cells usually shows a granular basophilic degeneration, when stained with one of the polychrome methylene blue dyes.

Lead palsy is rare in acute plumbism, but fairly common in chronic. It is a motor paralysis affecting those muscles which have been subjected to greatest use; in painters, the extensors of the wrist; in file cutters, the interosseous muscles of the hands; in lead smelters, the muscles of the upper arm and shoulder; and in children, the muscles of the foot and ankle. The cerebral form of plumbism, known as lead encephalopathy, is usually seen only after rapid intoxication by a massive ex-

posure to lead dust or fumes. It is characterized by epileptiform convulsions, acute delirium, and partial or total blindness. It may end in death, or in recovery, or pass into lasting insanity.<sup>14</sup>

Chronic lead poisoning is far more common in industry than is the acute form. It is characterized by increasing anemia, the number of corpuscles falling sometimes to half normal; by indigestion due to atrophy of the gastric mucosa; arteriosclerosis, resulting in interference with the blood supply of heart and kidneys and sometimes of the brain; lead palsy, lead insanity or apoplexy; a lowered resistance to infection, especially to tuberculosis. From time to time there may be in the course of chronic plumbism a typical acute attack of lead colic.

The diagnosis of industrial lead poisoning is based on the grayish pallor; the pinched appearance of the face; the lead line; loss of appetite; disagreeable sweetish taste; sense of weariness disproportionate to the exertion; loss of strength; loss of weight; gastric distress; constipation; disturbed sleep. Aids to diagnosis are the detection of lead in the urine or feces and the discovery of stippled red blood cells, which to be significant must number more than 100 out of a million.

Fetal death and abortion are common in maternal lead poisoning. Legge abstracted from reports of the British Factory Inspection Department for 1897 the following statistics concerning women lead workers: Of 77 married women, 15 never became pregnant; 15 of the 62 who became pregnant never bore a living child; among the 62 there were in all 212 pregnancies, but these resulted in only 61 living children, 21 stillbirths, miscarriages 90, and of the 101 children born alive, 40 died soon after birth. Tardieu reported to the French Government in 1905 that 608 out of 1,000 pregnancies in lead workers had resulted in premature birth. The offspring may even be affected when the mother is normal but the father "leaded."

Cole and Bachhuber<sup>15</sup> fed lead acetate to rabbits and fowls. In the rabbits the mortality of the young during the first four days after birth was 47.7 per cent. for offspring of "leaded" males, as contrasted with 29.2 per cent. for offspring of normal males. The average weight at birth was 48.9 grams for the former and 59.0 grams for the latter. With Leghorn hens the results were similar. Weller<sup>16</sup> used commercial white lead (basic carbonate), which he fed in capsules to guinea-pigs. The experiments showed that paternal lead poisoning in guinea-pigs does not result in sterility or in stillbirth, but in reduction of weight at birth, and this underweight persists through life. Next to this, the most strik-

<sup>14</sup> Paul cited in G. C. Nijhoff's article on "Action on Ovum of Superfluous Semen," *Nederl. Tijdschr. v. Geneeskunde*, Amsterdam, II, No. 16.

The Effect on the Offspring of Lead Poisoning in the Father: *J. A. M. A.*, Dec. 25, 1915, LXV, No. 26.

ing change is the high rate of mortality during the first few days after birth.

The character of certain occupations has an influence on the type of lead poisoning which develops. Thus Teleky finds that, while compositors in Vienna seldom suffer from colic or from the severer types of lead poisoning, they are subject to an unusual extent to diseases of the lungs and kidneys. The relation between tuberculosis and chronic plumbism is shown in Hahn's diagrams based on the records of typographical trades in Vienna and Berlin, the curves of the two diseases showing a remarkable parallelism. Colic is said by Legge to be most frequent among workers in white lead, red lead, enameling, storage-batteries, coach-painting (which involves sandpapering), while the severer form with paralysis is found in brass-workers, plumbers, printers, file-cutters, and tinsmiths. The former are very dusty trades; poisoning occurs rapidly and encephalopathy is more frequent than paralysis.

The manner in which lead is handled makes a vast difference so far as the liability to plumbism is concerned. Thus Stüler found in Vienna that carriage painters are ten to twenty times more subject to lead poisoning than house painters. This has been confirmed by Edsall in this country. The reason for this is that carriage painters apply a large number of coats of paint and varnish, polishing between coats, and thereby enveloping themselves in dust which contains much lead; furthermore, carriage painters are required to work indoors. For lead poisoning due to water see page 1155.

**Lead Oxids, Litharge and Red Lead.**—In the manufacture of litharge and red lead, the metal is roasted in reverberatory furnaces and raked from time to time. The raking or rabbling and the discharge from the furnace may be mechanical, in which case the danger from fumes and dust is very much lessened. The oxids are light and fluffy and it is hard to control the dust produced in dumping, grinding, sifting and packing them, and although great improvements have taken place in many oxid works of late years, the rate of plumbism in this industry is still fairly high.

The oxids are used in making storage batteries, the plates of which are leaden grids with a paste of litharge or red lead rubbed into the interstices. This industry is recognized in all countries as one of the most dangerous of the lead trades. Litharge is also used in rubber compounding, and men employed in weighing out the compounds and on the mixing mills may suffer from lead poisoning. Red lead is used as paint for bridges, structural iron work, certain parts of railway cars, and ships—especially battleships. Stitt<sup>17</sup> reported three cases of lead poisoning and encephalopathy in men who were chipping old red lead paint from the bottoms of battleships. Red lead is also used in making

<sup>17</sup> *U. S. Naval Med. Bull.*, 1912, Vol. VI, p. 161.

glazes for tiles and terra cotta, and enamel for porcelain enameled sanitary ware, and in these occupations there is a great deal of industrial plumbism.

**White Lead.**—Most of the white lead is still made by the old Dutch method, which consists in the transformation of metallic lead into the white carbonate by a slow and double process of conversion. Numerous earthenware pots containing 3 per cent. of acetic acid are placed on tan bark in a large three-walled chamber, and upon these pots are laid thin

FIG. 156.—A WORKER WITH LEAD OXID, SHOWING RESPIRATOR TO PROTECT HIMSELF AGAINST THE POISONOUS DUST. (Mass. State Board of Health.)

strips of metallic lead and subsequently planks of wood. Tier after tier of pots resting on bark and covered with metallic lead and wood are thus superimposed until the chamber, 25 or 30 feet in height, is filled to within 6 feet from the top. This chamber, known as the "blue" bed, is kept closed for 14 weeks or longer. Fermentation causes a rise in temperature and a production of carbonic acid. The acetic acid acts upon the lead and converts it into acetate of lead, while the  $\text{CO}_2$  evolved from the bark changes the acetate into carbonate or the well-known white lead of commerce. The danger of plumbism occurs during the emptying or stripping of what is now called the "white" bed. If sufficient time has not been given for the very soluble acetate to have become changed into the carbonate the danger is thereby greater. During the stripping of

the "white" bed there is a considerable quantity of dust raised, a large part of which is white lead.

Legge found that of 1,463 persons employed off and on in white lead works the incidence of lead poisoning was 6 per cent. of the average number regularly employed, and in those casually employed 39 per cent. This shows the great risk of exposing unskilled labor in a dangerous occupation.

In making so-called pulp lead, the white lead suspended in water is not dried but is ground in oil which gradually displaces the water, a method involving far less risk of poisoning.

The Carter process, much used at present in the United States, is a rapid corrosion of atomized lead, the great advantage of which is that it is largely mechanical and requires very little labor in proportion to output.

**The Manufacture of Pottery and Earthenware.**—Lead poisoning in potteries and tile works has been notorious for years in Europe. In England and Germany, especially, great efforts have been made to protect the workers against this danger. Aside from the precautions taken to avoid dust and other dangers in potteries, the English use a great deal of leadless glaze, and when this is not possible they frit the lead, that is, they fuse it with the other constituents of the glaze, thus changing soluble white lead or red lead in part or wholly to the insoluble disilicate. This is not done in American potteries where the glaze is fritted, but the lead is added subsequently. It is also unfortunately true that American potteries cannot bear comparison with British or German potteries in respect to construction or cleanliness or personal protection of the workers, and there is much more lead poisoning among the men and women potters in America than in Europe.

The chief centers for the manufacture of table and toilet ware, sanitary earthenware, so-called art pottery, and tiles, are Trenton, New Jersey, and the East Liverpool and Zanesville districts of Ohio. The work of glazing and decorating the pottery carries with it the danger of lead poisoning, although it is only decoration with lead colors that is dangerous: decalcomania or the use of lithotransfer paper is not attended with any danger. The glazes used in white ware potteries in 1911 contained from 1.75 to 33.3 per cent. of white lead. In the potteries making art and utility ware (yellow ware), and in the tile works, the glazes contained from 5 to 60 per cent. of white, more rarely red lead. The dangerous processes are mixing the glaze, dipping the ware in the glaze, cleaning the dipped ware to get rid of the excess of glaze, and stacking it on boards or trays to be fired, firing it in the glost kilns, and decorating it by the processes known as color blowing, or tinting and ground laying.

The difference between the sanitary control of this industry in

England and in the United States is shown by the rate of plumbism in the two countries. In English potteries in 1910, the morbidity rate for plumbism was 0.8 per cent. for men and 1.5 per cent. for women, while in 68 American potteries and tile works in 1911 the rate was 8 per cent. for men and 14 per cent. for women.<sup>18</sup> Since that year improvements have been introduced in American potteries, but they are not yet nearly up to the English standard.

**Lead Mining, Lead Smelting and Refining.**—In lead mining there is little danger of poison, for the ore is chiefly sulphid which is only sparingly soluble in human gastric juice. Smelting and refining of the ore are industries attended with a great deal of plumbism from both dust and fumes. In smelting, the greatest danger is found in the work at the open hearths, the blast furnaces, and the cleaning out of flues and bag houses; in refineries the danger from fumes should not be so great, but there is more dust because the refineries work up not only lead bullion but all varieties of lead scrap and refuse, some of which is very powdery and fluffy. The industry in the United States employed in 1913 some 7,500 men, and the rate of lead poisoning was over 22 per cent., whereas in England during the previous year the rate was 1.8 per cent. among about 2,000 men.<sup>19</sup>

**Miscellaneous Industries.**—Layet computed that in France 111 industrial processes involved the use of lead. Hamilton found 70 such processes in Illinois in which lead or its compounds are handled and which have caused lead poisoning in recent times.<sup>20</sup>

Some of the industries in addition to those mentioned above in which lead poisoning may occur are: making and selling wall paper; retouching photographs with white lead paint for catalogues and advertisements; polishing brass (the alloy containing lead); polishing cut glass with lead putty powder; mixing compounds for rubber. Other trades that use metallic lead are very numerous, including the making of wire, sheet, piping, plumbers' goods, machine parts, tinfoil, car seals and can seals, picture frames, trimmings for coffins, and the use of solder and Babbitt. The most important one, however, is the printer's trade, where the amount of lead dust and fume is slight, but long continued exposure brings about a serious form of chronic plumbism marked especially by a lowered resistance to tuberculosis.

Certain occupations which are dwelt on in the European literature as sources of serious lead poisoning are fairly free from this danger in the United States because our methods are different. File cutting is one of these, the file being strapped to a strip of lead; another is diamond polishing, the jewel being imbedded in lead. Very little jewel

<sup>18</sup> *Bull. No. 104*, U. S. Bureau of Labor Statistics.

<sup>19</sup> *Bull. No. 141*, U. S. Bureau of Labor Statistics.

<sup>20</sup> *J. A. M. A.*, 1911, Vol. LVI, p. 1240.

polishing of this sort is done in the United States and file cutting is mostly done by machinery. Europeans also use lead colors in printing textiles and dyeing them, as we do not, and while we plate kitchen ware with a lead-free enamel or with a pure tin, they plate it with a mixture of tin and lead, often a large proportion of the latter.

### PREVENTION

The prevention of lead poisoning rests, in the main, upon the fact that the lead comes to the workman usually as dust, sometimes as fumes through the air, but it must be remembered that lead is also carried to the mouth by deposits on the hands and other objects. Practical efforts for the protection of lead workers must be directed first to the prevention of dust and the removal of fumes; second to provisions for bodily cleanliness.

The first essential then is to keep the air which the workman breathes and which surrounds him free of lead. Most cases of lead poisoning could be averted by a proper system of ventilation. Certain processes should be carried on under hoods with a strong draft, or in cabinets, or in special rooms with an air current so arranged that the lead is kept away from the mouth, nose, hands, and clothes of those who are exposed.

On the part of the workman the prevention of lead poisoning consists in cleanliness of the hands and of the finger nails, frequent bathing, and the use of special clothing while at work. Care must be taken not to carry the fingers, which may be contaminated with lead, to the mouth and nose, and to wash the hands thoroughly before eating. Workmen should never take their lunch in the rooms where there is a suspicion of lead in the air. The hazard of chewing tobacco under such circumstances is obvious. Respirators may afford protection in emergency and short exposure, but cannot be depended on as a routine precaution, because the workmen will not wear them continuously.

Cleanliness is one of the all-essential requirements. A special room for the clothes of the workmen and special overalls should be provided for those who are exposed to lead. It is ignorance of the danger and the want of personal cleanliness that make casual labor in lead works especially dangerous. Even the women who wash the clothes of the workmen employed in lead factories may sometimes suffer from lead poisoning. Lavatories should be provided at the factory and the hands should be washed with water containing a small quantity of acetic acid followed by a liberal allowance of soap.

Workmen should alternate employment and not remain too long in the dangerous departments. Supplanting hand labor by machinery diminishes the number exposed to the risk. A medical inspection is an

important preventive guard in educating the workmen and in detecting mild and beginning cases.

A radical measure would be the substitution of zinc-white for lead paints. Zinc may be used as a substitute for lead, especially in indoor work; in fact this has been required by law in France. White lead appears to be superior to zinc for outdoor work.

Keeping down the hyperacidity of the gastric juice is believed to be a good preventive measure. This may be accomplished in part by taking a bland oil or drinking milk at intervals during work. Milk also acts by fixing the HCl of the gastric juice by the milk proteins. The milk should be taken between meals (say 10 a. m. and 4 p. m.) for in some persons there is considerable secretion of gastric juice in the empty stomach.

The Massachusetts State Board of Health issues the following protective measures against lead poisoning:<sup>21</sup>

The poison gains entrance into the system:

- (1) By swallowing minute particles of lead.
- (2) By inhaling lead dust or the fumes of lead in a molten state, or the vapor of lead in a fused state.
- (3) By absorption from the skin in handling lead.

#### *Advice to Employees*

- (1) General personal cleanliness is of the first importance.
- (2) Thoroughly clean your hands before touching food and before leaving the workroom.
- (3) Thoroughly rinse your mouth before eating.
- (4) Take good, nutritious food and plenty of milk.
- (5) Take a substantial breakfast; an empty stomach is more susceptible to the poisonous effects of lead.
- (6) Never eat at your work. Eat your luncheon outside of the workroom if possible; if not, in a part of the room away from the lead. Never smoke or use tobacco in any form while at work.
- (7) Avoid all excesses; alcoholic beverages are especially injurious.
- (8) Wear overalls or a long coat at your work; also a cap or some head covering. Whenever practicable wear gloves when lead is to be handled.
- (9) Persons working in white lead or other powdered compounds of lead should always wear a respirator while at work. Cause as little dust as possible.
- (10) Consult a physician at the first sign of ill health.

#### *Advice to Employers*

- (1) Provide washing facilities, lockers, and a place for the employees to eat luncheons away from lead.

<sup>21</sup> See also *U. S. Public Health Reports*, Dec. 19, 1919, p. 2905.

(2) Provide respirators for all the workers who have to handle white lead or other powdered compounds of lead.

(3) The floors of the workrooms and benches at which men work should be cleaned daily after thoroughly moistening them.

(4) These regulations should be posted in a conspicuous place in the workroom.

### PHOSPHORUS

There are two kinds of phosphorus: (1) the white or yellow, discovered by Brandt of Hamburg in 1669, (2) the red or amorphous, discovered by Schröter of Vienna in 1845. The amorphous phosphorus is obtained from the white phosphorus by exposing it in a closed vessel for some time to a temperature of 250° C. The white or yellow phosphorus is poisonous and has been the cause of much suffering in the match industry. The red or amorphous phosphorus is practically not poisonous.<sup>22</sup>

Three kinds of matches are made: (1) The safety match, which contains no phosphorus and is harmless. The match heads contain potassium chlorate or chromate and other compounds rich in oxygen from which the oxygen required to induce conflagration is evolved. The paste applied to the side of the match-box contains antimony sulphid and red phosphorus. (2) The strike-anywhere match contains the poisonous white phosphorus in the head, and in addition glue, chlorate of potassium, powdered glass, and magenta or some other coloring agent. The paste, or composition, contains on an average 5 per cent. of phosphorus. It is in mixing this paste, especially when done by hand in open vessels, and also in dipping the wooden splints, that the work-people are exposed to fumes that become a menace to health. (3) The strike-anywhere match made with the non-poisonous sesquisulphid of phosphorus.

When pure, phosphorus is colorless and transparent, but when exposed to the light it becomes yellowish. The white and yellow forms are extremely poisonous; the red and amorphous phosphorus can be handled with impunity. Red phosphorus does not take fire when rubbed on a rough surface. It is non-volatile and when swallowed is, comparatively speaking, non-poisonous. One to 3 grains of white phosphorus will cause death. The fumes from white or yellow phosphorus are rich in phosphorus oxids and these are absorbed in various ways.

Several years ago the Belgian government offered a prize of 50,000 francs to any person who would invent a safety strike-anywhere match free from white phosphorus. The problem was solved by Sevène and Cahan of France, who demonstrated that the sesquisulphid of phosphorus would accomplish all that white phosphorus does without causing pois-

<sup>22</sup> Phosphorus Poisoning in the Match Industry, by J. B. Andrews, *Bull. 86, U. S. Bureau of Labor.*

oning. The sesquisulphid is an almost inodorous powder and is, practically speaking, non-poisonous. It contains a trace of red or amorphous phosphorus. Since the introduction into France of the manufacture of the sesquisulphid match there has not been in the factories of that country, where the manufacture of matches is a state monopoly, one case of phosphorus poisoning, nor has there been any explosion or fire in any of the match works. It has been found that the sesquisulphid of phosphorus acts, in some instances, as an irritant, causing conjunctivitis and edema of the eyelids, also eczema of the skin. This may be obviated by bathing the eyes and douching the nostrils twice a day before leaving the factory with an alkaline solution of bicarbonate of soda.

White phosphorus lucifer matches were first made in 1833 and the disease known as "phossy jaw" was first reported by Lorinser of Vienna in 1845. Soon after that, similar cases were reported from practically all European countries. In the United States, lucifer matches were first made in Springfield, Massachusetts, in 1836, and in 1851 there was the first description of a case of phossy jaw in America, a man who was treated in the Massachusetts General Hospital. The effects of phosphorus poisoning in match workers attracted widespread attention because of its painfulness and its disfiguring effects, and it was not long before the public in all European countries began to agitate against the conditions giving rise to it and to demand their abolition. After all forms of governmental regulation had been tried without success, the principal countries of Europe entered into an agreement, the Berne Convention of 1906, by which the manufacture, importation, and sale of white phosphorus matches were prohibited. The United States was not a party to this agreement, and, at this time and for several years after, there was a general belief in this country that our superior methods and our factory sanitation had driven phossy jaw out of American match factories, but the thorough investigation carried on by John B. Andrews in 1910 showed that this was a fallacy. He discovered a total of 150 cases of phosphorus poisoning in the match industry, some of them very severe, attended with shocking disfigurement, and four of them fatal. The publication of his report resulted in the passage of the Esch Law in 1912, which placed a prohibitive tax on white phosphorus matches. In 1913 their importation became illegal and the following year their exportation.

The reason for the widespread attention given to phossy jaw is not its great prevalence—for only a small proportion of those exposed suffer—nor because it is very dangerous to life, for the mortality is about 15 per cent. It is, however, extremely painful and the results are dramatically visible to everyone. It attacks the bones of the jaw, producing deformities and disfigurements, and it is accompanied by a distressingly fetid discharge. The action of the phosphorus fumes takes

place through a defective tooth or through the wound left by the extraction of a tooth, and the fumes reach the periosteum of the jaw-bones, upper or lower, or both. A necrotic process sets in and then infection by suppurative germs in the mouth causes abscess formation with intense suffering. Abscesses in the upper jaw discharge on the cheek or into the mouth, those of the lower jaw make their way down on the neck. Absorption from the suppurative process causes cachexia, which renders the victims an easy prey for tuberculosis, or they may die of chronic septicemia. In rarer cases, the periosteum of other bones is attacked, rendering them brittle and liable to fracture under very slight violence (*fragilitas ossium*).

The matches now made are the red phosphorus safety match, and "strike anywhere" matches made with the sesquisulphid, neither of which is poisonous.

### ARSENIC

Arsenic acts as an irritant to the skin and mucous membranes, setting up conjunctivitis, coryza, eczema and ulcerations: it also produces general poisoning, causing anemia and neuritis and degenerative changes in liver and kidneys. Arsenical neuritis is particularly severe.

Arsenic is present in almost all the sulphid ores of the metals and is therefore encountered in iron, lead, zinc and copper smelting. The flue dust of the western lead smelters contains large quantities which are recovered by sublimation as white arsenic—the trioxid, used in various industrial processes. The other compounds of arsenic which are industrially important are lead arsenate and the aceto-arsenite of copper, or Paris green, both of which are used to kill insects and parasites. White arsenic is used as a sheep dip, and a preservative for hides, skins and feathers. It is also used in curing furs. The Massachusetts law forbids more than one grain of arsenic per square yard, but analyses reveal that it often reaches 170 grains. Out of 42 samples of fur recently examined in America, 11 were found heavily loaded with arsenic. The presence of such large quantities of arsenic in furs that are worn or in rugs for rooms must be a source of danger. Another danger in former years came from the use of arsenical colors in wall papers and textiles, but this is no longer a serious matter in the United States. The Massachusetts law of 1900 limited the amount of arsenic in wall paper to 0.1 grain per square yard, and in textiles for clothing to 0.01 grain. In 1904, an investigation made by the U. S. Department of Agriculture showed that only 4 out of 537 samples of wall paper had more than 0.1 grain per square yard.

Workers in compounds of arsenic often present general symptoms resembling those of lead poisoning; namely, anemia, loss of strength, loss of appetite, gastric disturbances, but instead of palsy of certain

muscles there is a painful neuritis and the arsenical worker suffers from lesions of the skin which serve to distinguish this form of poisoning very sharply from plumbism. Workers in Paris green suffer from painful redness of the eyes and from eczema of the eyelids, they have painful ulcers around the lips and nostrils and in the folds of the skin where the perspiration collects. Ulcers of the scrotum are particularly common.

During the latter part of 1900, there occurred in England and Wales an epidemic of arsenic poisoning, affecting at least 6,000 persons. The districts principally affected were in Lancashire and Staffordshire. The cause was arsenic which contaminated beer from breweries that used glucose and invert sugar from a single firm.

From 0.008 to 0.131 per cent. of arsenic was found in the glucose, and from 0.02 to 0.062 per cent. in the invert sugar, estimated as arsenous oxid. The arsenic came from the sulphuric acid, used to hydrolyze the starch to make the glucose and invert sugar, and contained from 1.4 to 2.6 per cent. of arsenous oxid.

Arsenic, as well as other irritants, is believed to predispose the tissues to growths of a cancerous nature.

*Arseniuretted Hydrogen* ( $AsH_3$ ).—More serious than arsenical dust is the gas, hydrogen arsenid, commonly called arseniuretted hydrogen, which is accidentally evolved in the course of many industrial processes. The effects of this gas often fail to be recognized because the presence of the arsenic is not suspected. Almost all of the metals used in industry are derived from arsenic-bearing ores, and are therefore frequently contaminated with arsenic. The larger part of the sulphuric acid used in industry is made from iron sulphid or pyrites, and may also have traces of arsenic. Whenever, therefore, such an acid and metal come in contact, hydrogen arsenid may be given off and severe, often fatal poisoning results from the inhalation of the gas. Workmen cleaning out or repairing iron tanks, which have held arsenic, have been poisoned in this way. Other occupations which involve this danger are the production of hydrogen from zinc dust and hydrochloric acid, and the use of such hydrogen for the flame of the lead burner and for filling balloons. Similar accidents have occurred in making acids from arsenic-bearing compounds; treating waste zinc from a galvanizing plant with hydrochloric acid to make zinc chlorid; pickling metals, i. e., dipping in acid in preparation for plating or enameling; recovering copper by electrolysis.

Arsenic is no longer used in the manufacture of aniline dyes, but arsenical poisoning sometimes occurs accidentally in dye manufacture during the process of reduction which requires the use of metallic dust and acid. Recently wholesale poisoning from this gas occurred on a British submarine, the source being the storage batteries in which acid

came in contact with plates made from an antimony-lead alloy which contained arsenic.

The symptoms of this form of poisoning are quite different from that caused by arsenical dusts. There is a rapid onset, with nausea, vomiting, pain in the epigastrium, headache, dizziness, dark or even bloody urine. The red blood corpuscles undergo a rapid destruction, falling sometimes to less than a million, and the liver and kidneys in fatal cases are found in a condition of hemorrhagic inflammation. The mortality in industrial cases is about 36 per cent.<sup>23</sup>

### MERCURY

Mercurial poisoning<sup>24</sup> may be contracted by workmen employed in extracting mercury from cinnabar (sulphid of mercury), in which it is usually found in nature. The ore is simply roasted and the mercury volatilizes and readily condenses in metallic form. Mercury volatilizes at a low temperature and it is this circumstance which creates much of the danger to those who work with this substance, especially to men who work in a closed and heated atmosphere containing the vapor given off by the metal. Mercury is absorbed by the digestive system, by the respiratory tract, and also through the skin. As an instance of the absorption of mercury through the skin Edsall cites two cases in dentists who were poisoned as a result of the custom found in many dentists of working up their amalgam in the palms of their hands.

The occupations in which mercury is used and in which mercurial poisoning occurs are: the separation of gold and silver from their respective ores, which is done by means of an amalgam; the manufacture of incandescent lamps, in which mercury pumps are used, to create a vacuum; in barometer and thermometer making; in felt-hat and fur dressing, in which mercuric nitrate is used; in water-gilding, where an amalgam of gold or silver, after having been applied to an object, is heated and the mercury driven off; and other industries.

The New York and New Jersey section of the National Civic Federation in three months' time found 60 cases of mercurial poisoning, a nervous disease called in the trade "the shakes," among the hat makers of Brooklyn, Newark, and Orange as a result of the mercury salts used in preparing felt.

The symptoms of mercurial poisoning are: anemia, headache, dizziness, tremor of the muscles, especially the tongue and limbs, fetid breath, soft, swollen, and ulcerated gums, and loosening of the teeth. The submaxillary and other glands of the neck become painful and the secretion

<sup>23</sup> T. M. Legge in Kober and Hanson's "Diseases of Occupation," page 3, Philadelphia, 1916.

<sup>24</sup> Report of Mercurial Poisoning in the Industries of New York and Vicinity: L. W. Bates, *National Civic Federation*, 1912.

of saliva excessive. Erethism and apprehensiveness are common; in severe cases depression and melancholia. A persistent and apparently causeless diarrhea is frequently a symptom of mercurial poisoning.

#### PREVENTION

The prevention of mercury poisoning is almost a direct counterpart of the prevention of lead poisoning. The air must be kept free of mercury, and this can be accomplished by proper systems of ventilation, by the use of hoods with forced draft and other devices to keep the mercury fumes away from the workmen. Rubber gloves may be worn to prevent absorption through the skin and also to prevent the carrying of the mercury to the mouth. Here again scrupulous cleanliness in and after leaving the workroom, a change of clothing, and washing the hands before eating are essential.

Other metallic poisons found in the industries are antimony, brass (an alloy of copper and zinc with more or less lead), chromium, manganese, vanadium, and selenium.

#### CARBON MONOXID

Carbon monoxid is a colorless, inodorous, and highly poisonous gas. It burns with a pale blue flame. It is one of the products of the incomplete combustion of illuminating gas, also of coal and explosives. It is met with in coal mines and other subterranean galleries where blasting has been effected by dynamite and gun-powder. It forms 7 to 10 per cent. of ordinary illuminating gas (coal gas) and 30 per cent. of water gas. It is the source of blue flame seen on the surface of an ordinary coal fire. The gas is given off in quantities from coke ovens; it is evolved from blasting furnaces in the smelting of iron, especially during the charging of furnaces and their tapping. Carbon monoxid frequently remains in the furnace, and workmen who enter such a furnace in order to clean it may be overcome. In England the law requires two workmen to clean furnaces; one stands by in case of accident. Carbon monoxid is also evolved from hot-water heaters; in the Leblanc process of soda manufacture; in cement and brick works, from the use of producer gas and a fuel oil. Carbon monoxid is given off in the exhaust gases from motor cars, and is responsible for the serious poisoning, often fatal, which has occurred when the engine of a motor has been allowed to run in a closed garage. Such accidents used to be called "petromortis" under the impression that the fumes came from the gasoline.

The poisonous properties of carbon monoxid are, according to Haldane, due to the great affinity it has for the hemoglobin of the red corpuscles. It has from 140 to 250 times greater chemical affinity for hemoglobin than oxygen. It forms carbon monoxid hemoglobin, a more

stable compound than oxyhemoglobin, and therefore prevents the oxygen being given to the tissues. When the percentage of carbon monoxid rises to 0.4 the atmosphere becomes dangerous to animal life. See page 941.

The inhalation of carbon monoxid causes headache and a sense of loss of power in the lower extremities. It is this circumstance which explains many of the cases of fatal poisoning in confined spaces. There are also dizziness, throbbing of the temples, ringing in the ears, a sense of lassitude, and, in severe cases, convulsions and loss of consciousness. The inhalation of small quantities also leads to delusions and other mental symptoms. If the gas enters a bedroom and is inhaled by persons who are asleep the sleep only becomes deeper and profound narcosis is developed from which there may be no awakening.<sup>25</sup> The damage done to the cells of the brain and cord may be permanent, paralysis and mental symptoms persisting after recovery from the immediate effects of the gassing.

Oliver gives the following illustration of the subtle poisoning by carbon monoxid at Pelton Fell, a mining village in Durham County. Some shale which had been tipped at the edge of a ravine caught fire. The carbon monoxid gas given off during the combustion traveled through the soil and entered two houses in different streets, full 30 feet away, causing the death of two elderly people. It is to the breathing of this gas during sleep that the death of tramps, drawn to the coke ovens by their inviting warmth on a winter's night, is attributed. I have already instanced the case of death from carbon monoxid resulting from the imperfect operation of a gas water-heater. See page 945.

### HYDROGEN SULPHID

Hydrogen sulphid is an extremely poisonous gas causing death instantaneously if inhaled in large quantities. In smaller amounts the symptoms caused are nausea, vertigo, headache, general malaise, all of which soon disappear if the workman goes into the open air.

The industrial processes in which hydrogen sulphid gas may be encountered are the decomposition of sulphids by acids in chemical works: the production of sulphur compounds such as sulphur monochlorid and barium trisulphid: the making of illuminating gas and coke by-products: the black bronzing of metals by means of sulphid of arsenic: the cleaning of boilers: certain processes of soap making where large quantities of fat are decomposed: the preparation of Prussian blue: the decomposition of ferrocyanid of potassium by sulphate of iron: the making of sulphur dyes, especially khaki.

In nature hydrogen sulphid is one of the products found during

<sup>25</sup> See also Bureau of Mines Technical Papers 156 and 106.

the putrefaction of organic matter containing sulphur. The gas may therefore be found about privies, the mud of marshes, and collections of filth and manure, but in quantities too small seriously to influence health. See page 947.

### OTHER INDUSTRIAL POISONS

**Benzol or benzene** is one of the coal-tar distillates, and is used either pure or as commercial benzene, which contains such impurities as xylene and toluene. Benzene is used as a solvent for rubber, also in the production of rubber, resin, iodine, phosphorus, sulphur and fats; and in the dyeing industry.

Benzene enters the body as a vapor, irritates the respiratory tract, and produces acute and chronic poisoning. In acute poisoning the symptoms are of respiratory and nervous origin and range from cough, vertigo, tinnitus, vomiting, perspiration and pruritus, to cyanosis, irregular pulse, anesthetics, delirium, convulsions, coma and death. In the chronic form there are purpuric hemorrhages from the mucous membranes of the mouth and nose and into the skin, fatty degeneration of the heart, kidneys and liver, anemia, an extraordinary leukopenia and death.

Benzene has been taken as a type of the volatile hydrocarbons, such as solvent naphtha, nitrobenzol, and other coal-tar derivatives.

**Anilin.**—Industrial poisoning from anilin and substances closely allied to it is well known in Germany and in Great Britain. It is just beginning to be known in the United States,<sup>26</sup> where it has already been the cause of many cases of poisoning among men engaged in the manufacture of rubber goods, in reclaiming rubber from scrap, in making anilin from benzene, and in using certain washes for press rollers. It also occurs in the dye industry. Anilin causes the formation of methemoglobin, and poisoning usually takes place through the skin, sometimes the lungs. It is commonly called "the blues" on account of the cyanosis produced.

Exposure to the fumes alone may cause poisoning, especially in the susceptible, but the most serious cases follow the spilling of anilin on the skin, and the first precaution to be taken in all cases of anilin poisoning is to make the man strip and take a full bath. Experience shows that skin absorption is far more important in industrial anilism than the breathing of fumes.

Early recognition of anilin poisoning is of prime importance, so that the sufferer may be withdrawn from the danger of further exposure. Men working constantly in anilin seem to acquire a certain amount of tolerance to it, but chronic poisoning may result apparently from cumu-

<sup>26</sup> Luce and Hamilton: "Industrial Anilin Poisoning in the U. S.," *J. A. M. A.*, May 6, 1916, LXVI, No. 19, pp. 1441-1445.

lative effect. After symptoms of poisoning have once manifested themselves, the individual is usually hypersensitive to the fumes.

**Manganese.**—Up to 1913, this rare form of industrial poisoning was not known to exist in the United States, but the researches of Casamajor<sup>27</sup> and of Edsall and Drinker<sup>28</sup> during recent years have brought to light some 39 cases, while the number reported from European countries is only 15. The poisonings follow exposure, usually for some months, to dust containing manganese dioxid. The symptoms were likened by von Jaksch and Seelert to those of multiple sclerosis, by Edsall and Drinker to progressive lenticular degeneration. The last two authors summarized the symptoms in such poisoning as follows: A history of work in manganese dust for at least three months; languor and sleepiness; muscular twitchings, from tremors to gross rhythmical movements of arms and legs, trunk and head; cramps and stiffness of the calves, usually at night; slight increase in tendon reflexes; ankle and patellar clonus; retropulsion and propulsion; peculiar slapping gait; occasionally uncontrollable laughter, less often weeping; absence of sensory, gastro-intestinal, eye, genito-urinary disturbances; negative blood, urine and spinal fluid findings.

**Carbon Disulphid.**—This is a powerful solvent for fats and gums and has long been used in the rubber industry for so-called cold or acid vulcanization. Sulphur monochlorid is dissolved in carbon disulphid and the rubber is dipped in the fluid or painted over with the fluid or hung in its vapors. This mode of vulcanization is not so generally used in the United States as in European countries.<sup>29</sup> The symptoms of carbon disulphid poison consist in excitement followed by depression and apathy. There is an increasing weariness and loss of strength, most marked in the legs, climbing stairs becomes difficult. There is usually drowsiness, even mental confusion, and sometimes severe headache and insomnia. In serious cases which come on rapidly, there is acute mania; in those that come on more slowly, paralysis. There may also be impairment of sight from atrophy of the optic nerve. Because of its inflammable character, carbon disulphid is gradually being replaced in rubber works by the non-inflammable and far less toxic carbon tetrachlorid. It is, however, coming into use in a new industry, the making of artificial silk.

**Brass.**—Brass is an alloy of copper and zinc, the cheaper varieties containing a large proportion of zinc and from 1 to 13 per cent. of lead. Brass founders' ague has been known for fully a century. It is an acute ague-like attack, coming on usually after exposure to the fumes of molten brass, but not until the man has left the shop and

<sup>27</sup> *J. A. M. A.*, 1913, Vol. LX, p. 646.

<sup>28</sup> *Journ. Industrial Hyg.*, 1919, Vol. I, p. 133.

<sup>29</sup> *Bull. No. 179, U. S. Bureau of Labor Statistics.*

gone into the cold air. He suffers from a severe chill, weakness, nausea, and then fever, sweating and prostration, but usually he is able to return to work the next day and hardly ever considers the attack serious enough to send for medical assistance. It is the zinc in the alloy, not the copper, that causes sickness, and it is only when volatilized in the form of fumes and inhaled that the effect is produced. Brass polishers do not suffer from "the shakes," and the sickness described as brass poisoning in brass polishers is often, if not always, lead poisoning

FIG. 157.—WORKMEN EXPOSED TO ZINC FUMES IN BRASS CASTING, CAUSING A CONDITION KNOWN AS "BRASS-FOUNDER'S AGUE."

from the dust of cheap brass containing lead. True brass founders' ague occurs also in braziers who weld together metallic surfaces with the aid of a solder containing brass; also in zinc smelters, and rarely in galvanizers working over a hot zinc bath, in autogenous welders working with zinc. The brass industry is generally considered more unhealthy than the average, for in addition to brass fumes and lead dust, workers are exposed to fumes of acids, of volatile solvents for shellac and lacquer, and to great heat.

**Wood Alcohol.**—Industrial wood alcohol poisoning has assumed great importance of late years in connection with the use of shellac, varnish, paint and varnish removers, the stiffening of felt hats, the making of celluloid and the making of dye intermediates and explosives.

In 1915, Tyson and Schoenberg<sup>30</sup> estimated that two and one-half million workers in the United States are exposed to wood alcohol by inhalation or contact in the course of their work, and they have discovered about 100 industrial cases. The effect of wood alcohol differs in many respects from that of grain alcohol. It acts more slowly, and is far more slowly eliminated. In a typical case, the workman suffers for some time from attacks of dizziness and headache and weakness, which gradually increase in severity, then he notices a dimness or fogginess before the eyes which may suddenly pass into complete blindness. This blindness is due to an optic neuritis, followed by atrophy and the result is partial or total permanent blindness. Severe poisoning causes death, preceded by blindness, convulsions and coma. See also page 94.

A revenue bill passed in 1906 permits the use in industry of grain alcohol denatured by the addition of 2 per cent., 4 per cent., 10 per cent., or 20 per cent. of wood alcohol, and 0.5 per cent. of pyridin bases. This is of course far safer than pure wood alcohol, but the use of the formulae containing the larger proportions of wood alcohol is not unattended with risk, for some people are decidedly susceptible and react to a small quantity of the poison.

**Other toxic gaseous vapors and fumes** occurring more or less commonly in industrial processes are: Acetaldehyd, acrolein, ammonia, amyl acetate, amyl alcohol, anilin and its oils, hydrogen sulphid, carbon monoxid, carburetted hydrogen, chlorin, diazomethane, dimethyl sulphate, dinitrobenzol, ether, ethyl nitrate, formaldehyd, hydrocyanic acid and cyanids, lydol and titron, methyl alcohol, naphtha and gasoline, nitrobenzol, nitrous gases, phosgene, phosphorus, phosphorated hydrogen, sulphur and sulphur dioxid, sulphurated hydrogen, turpentine and many others. Only a few of these have been discussed as examples. See also poisonous gases in the atmosphere, page 941.

### *DUSTY TRADES*<sup>31</sup>

Dust is the great enemy of the workman. Much ill health is caused by the inhalation of dust, some of which is also injurious when ingested and some of which is irritating to the skin, eyes, or exposed mucous membranes. Dust of all kinds, both organic and inorganic, is met with in the various industries. Organic dust is usually less irritating and dangerous than inorganic dust, which becomes harmful particularly when the particles are sharp and therefore irritating. The principal trades and occupations in which excessive amounts of dust are found are: all forms of grinding and many processes of polishing and cleaning; the textile industries; in the lead, copper, and iron trades irritating

<sup>30</sup> *J. A. M. A.*, 1914, Vol. LXIII, p. 915.

<sup>31</sup> See also page 931.

and poisonous dusts are raised; also in pottery works and masonry, and in the handling of leather, skins, feathers, wool, cotton, wood, paper, tobacco, cement, cutting diamonds and other precious stones; emery, glass, horn, bone and shell, grain and flour, etc. The amount of dust may be very great: <sup>31a</sup> thus Hesse found in one cubic meter of air the following amounts of dust in the occupations named:

Felt hat factory .....	175	milligrams
An old flour mill .....	48	"
A new flour mill .....	4	"
Mechanical knitting .....	3	"
Sculpturing .....	9	"
A paper factory .....	4-25	"
Iron works .....	72-100	"
A coal mine .....	14	"
A living room .....	0	"

The kinds of dust vary greatly in their hygienic significance. Some are poisonous, some act as mechanical irritants. The principal poisonous dusts found in the industries are lead, mercury, arsenic, manganese, and zinc; less often substances from tobacco, wood, dyes, and chemical works. The dust particles which act by mechanical irritation are especially the hard, irregular particles with sharp edges from iron, steel, and other metals; from granite, basalt, or marble; while those from coal, chalk, and plaster of Paris are less irritating.

According to Sommerfeld the following proportion of persons per thousand in the various dusty occupations mentioned die of pulmonary tuberculosis: <sup>32</sup>

Occupation without dust production .....	2.39
With dust production .....	5.42
With porcelain dust .....	14.0
With iron dust .....	5.55
With lead dust .....	7.79
With stone dust .....	34.9
With stone workers .....	4.3
With wood and paper dust .....	5.96
With tobacco dust .....	8.47

Persons exposed to excessive amounts of dust for long periods of time suffer from a general condition known as *pneumokoniosis*; when due to coal dust the condition is known as *anthracosis*; when due to stone dust, *siderosis* or *chalicosis*; when due to vegetable fibers such as cotton, *byssinosis*. The dust may, in part, be free in the alveoli of the lungs and in part is inclosed in the cells. The epithelial cells lining the alveoli act as phagocytes. At times some of the alveoli may be plugged

<sup>31a</sup> Winslow, C.-E. A., Greenburg, L., and Greenberg, D.: "The Dust Hazard in the Abrasive Industry." Rep. No. 530, P. H. Rpts., May 30, 1919, p. 1171; also, Miller, F. G., and Smith, H. F.: "The Dust Hazard in Certain Industries," *Jour. A. M. A.*, Mar. 2, 1918, Vol. LXX, No. 9, p. 599.

<sup>32</sup> F. L. Hoffman, "Mortality from Tuberculosis in Dusty Trades," *Bulls.* 79 and 82, U. S. Bureau of Labor.

with dust particles. Sometimes the dust remains in the lungs without any apparent reaction on the part of the tissues. Usually round cells appear in the interalveolar spaces, and other indications of irritation and inflammatory reaction take place, leading to connective tissue formation between the alveoli and thickening of the alveolar wall itself. This may progress to an indurative bronchitis; that is, several alveoli become drawn together by the contracting connective tissue into a nodule. Other

FIG. 158.—AN EFFECTIVE DUST-REMOVING SYSTEM IN THE BOOT-AND-SHOE INDUSTRY.

Edge trimming. (Mass. State Board of Health.)

forms of inflammation, such as nodular peribronchitis or nodular perivascularitis, may take place. The dust particles are also carried by the phagocytes to the regional lymphatics, where they lodge. These irritative processes cause a low grade inflammatory reaction which only awaits the coming of bacteria to start specific or destructive processes (page 927).

Some dust is especially irritating to the conjunctiva, as wood dust or arsenic. Certain kinds of dust are prone to cause chronic catarrhal inflammation of the upper respiratory passages, while dust containing specific microorganisms such as anthrax may lead to acute pneumonia (wool-sorter's pneumonia).

**General Principles of Prevention.**—Much of the dust raised in industrial processes may be limited by improvements in machinery or preventive devices. Sometimes the dust may be kept down by moisture, sprays, or even conducting the work under water when practicable. Certain dusty operations should be conducted in inclosed hoods or special cabinets so as to confine the dust and thus protect the work

FIG. 159.—A VERY DUSTY TRADE.

people, or the dust may be removed by suction fan devices. Good ventilation diminishes the danger very much. When workmen are compelled to stay in dusty atmospheres they should wear respiratory masks, and the number of persons thus exposed should be reduced to a minimum. Some exceedingly dusty processes, such as cleaning castings with a sand blast, demand the wearing of a protective headgear. Many workmen prefer taking chances to wearing uncomfortable respirators. For a further discussion of dust, smoke, etc., see Section VI.

### THE TEXTILE INDUSTRIES

The manufacture of cotton, linens, silk, and jute has received an unenviable reputation as a dangerous occupation, despite the fact that

these industries need not in themselves be particularly unhealthy occupations. The textile industries illustrate several points in the diseases of occupation. One is that an entire industry should not be condemned because one of its processes is attended with a certain amount of danger. The other is that the risks to health may be prevented or greatly ameliorated. General improvement in the sanitary conditions of textile mills is one of the promising signs of material advancement in industrial hygiene.

The principal conditions which affect health in the textile industries are: The working in a dusty atmosphere which is often kept very moist and usually very warm in order to keep the fiber pliable and workable. The humidity and temperature may be regulated, and by efficient systems of ventilation their ill effects may be minimized or even neutralized. The dust may also be lessened, and in the processes in which it is excessive the workmen may protect themselves with respirators.

Much dust is raised during the opening and emptying of the bales of the raw material. This is avoided in the better mills by the use of machinery. Most dust is raised during the process of "carding"; some during "roving," "spinning" the yarn, and "winding" it; and also considerable during "weaving." In linen factories the "hecklers," that is, the men who dress and sort the rough flax (converted into tow by having been passed through a machine), are exposed to considerable amounts of dust and suffer from dryness of the throat and bronchitis, attended by cough and shortness of breath. In the manufacture of sacks, twine, and carpets from jute the processes that are extremely dusty are the preparing and spinning. The dust given off by jute is irritating.

**Humidity in Textile Mills.**—Working in an atmosphere which is excessively moist and frequently very warm, and, further, containing an excessive amount of organic dust, subjects the workmen to artificial and unnatural conditions which cannot be conducive to health.<sup>33</sup> Presumably the heat and moisture predispose to rheumatic states and inflammatory conditions of the respiratory tract which are aggravated by the irritation of the fibrous dust. It is believed that workmen so exposed are more prone to contract common colds, bronchitis, pneumonia, tuberculosis, and other inflammatory diseases of the respiratory tract.

The humidity of the air is an important factor in the manufacture of textile fabrics. The former supremacy of certain English localities as textile centers was due to the naturally favorable climatic conditions. This led to the adoption of artificial means of increasing the moisture of the air in mills less favorably located. When the fibers contain a certain proportion of moisture they are elastic and cling closely together, and may be carded, combed, drawn out, and spun into yarn, and woven into cloth more easily than when dry. When the fiber is moist the work

<sup>33</sup> For effect of heat and humidity upon health see pages 904 and 964.

in all these processes runs better and smoother; finer grades of goods may be made from the same stock; there is less waste, and the machines may be run at higher speed with less attention from the operators. Yarn spun from dry fiber is harsh and kinky; it does not retain its twist and breaks easily; furthermore, there is more dust and "fly" which menace the health and comfort of the work people.

The temperature and humidity most suitable for obtaining the best results in each process with material of different character and quality have been determined with considerable care, and, generally speaking, have been found to be such as would not be prejudicial to health. Despite this knowledge excessive moisture and high temperatures injurious both to health and to the processes of manufacture are found in some mills.

The necessary humidity in textile mills is obtained by a number of different devices. The methods which depend upon the introduction of moisture directly into the mill rooms are more objectionable than the humidification of the air forced into the rooms by some system of mechanical ventilation. In any case, the water used to moisten the air should be clean and free from odor or objectionable impurities.

The simplest method of producing artificial humidity in mill rooms is by sprinkling water upon the floor and trusting to natural evaporation. This method, known as "degging," was widely practiced at one time, and is still occasionally found in some foreign mills. Degging was replaced by shallow channels in the floor for the water, or by the placing of pans of water about the room, and later by introducing steam directly into the room. Steam is objectionable for the reason that it unduly increases the temperature. The modern types of humidifying apparatus depend upon moistening the air by passing it over water surfaces or through water curtains. The spray moisteners are made in a large variety of patterns. Some are constructed on the principle of the common household atomizer.

In Massachusetts there is a law regulating the amount of humidity and temperature in the textile mills which is based upon the English schedule contained in the Weaver's act of 1870. The conditions in Massachusetts, however, are so different from those found in England, especially in the summer time, that the schedule has not been found practical. Much of the ill effects in the textile industries may be neutralized by good ventilation, abundant air space, cleanliness, sufficient light, and the use of improved machinery. Special rooms should be provided for the clothes, in order that the moist garments may be changed for dry ones before the work people go into the open air, thus avoiding the chilling effects of damp garments.

*WOOD DUST*

It is well known that workers in wood are subject to the mechanical effects of ordinary sawdust, which is moderately irritating. Workers with boxwood, teak, and sequoia (redwood) are subject also to the general poisonous effects of alkaloids and other substances contained in these woods which may have more marked general effects, especially on the circulation and, still more frequently, marked local effect on the mucous membranes and the skin. In 1902 Young observed that men working with Maracaibo boxwood complained of dryness of the throat and inflammation of the eyes which lasted two or three days. This wood is used in the making of rulers. Oliver notes that joiners that saw and chip sequoia wood suffer with symptoms resembling a bad cold in the head and chest; a tolerance seems to be established except by men who are liable to bronchitis and asthma. Wounds caused by splinters of the wood invariably suppurate and do not heal readily. Oliver found that rats were also susceptible to sequoia sawdust. They suffer from a running at the nostrils.

Certain kinds of wood have a bad reputation among joiners. Some sawdusts are more irritating than others, probably from the large amount of inorganic matter they contain. A West African boxwood from which shuttles are made causes headache, coryza, excessive secretion of tears, and attacks of asthma. These woods contain alkaloids, glucosids, and other extractives. Workers in teakwood occasionally suffer from dermatitis.

*MINING*

Coal mining is one of the dangerous and unhealthy occupations. The dust, the unnatural conditions under which the miner is compelled to work underground, the poor air, and sometimes exposure to poisonous fumes all conspire to make this occupation one attended with unusual risks. The unsatisfactory methods for disposal of feces often found in mines favor the spread of hookworm and other parasites. To this must be added the danger of accidents and explosions.

The conditions of mines have been greatly improved, especially through better systems of ventilation, through the use of safety lamps, through reduction of the amount of dust, the regulation of the hours of occupation, and devices to detect poisonous and explosive gases. The sanitation and cleanliness of mines have also shown development. As an illustration of some of the complications and difficulties of this subject, reference is made to the fact that moisture will prevent explosion in mines. Moisture was, therefore, introduced into some of the German mines with good results, so far as explosions are concerned, but the moisture favored the development of the hookworm larvae and hence

caused such a great increase in the amount of hookworm infection that it became necessary to seek other methods.

The mortality from accidents and diseases of the lungs is high. Coal miners' phthisis, or anthracosis, is a well-known disease. Although coal is a vegetable product the result largely of microbial action, fresh coal is free from microorganisms. Oliver points out that in some of the mining centers colliers not only suffer less from pulmonary tuberculosis than persons in other occupations, but that they also suffer unequally in dif-

FIG. 160.—THE STONE INDUSTRY.

The workman is using a surfacing machine operated with compressed air. The strong blast of air keeps the granite clean, but gives rise to a great amount of dust. Of the mineral dusts granite is generally considered as most irritating. (Mass. State Board of Health.)

ferent mining centers. Why this is so it is difficult to say. While the death rate from pulmonary tuberculosis in miners is in some places low, that due to non-tuberculous affections of the lungs is, comparatively speaking, high.

DeCrocq speaks of the rarity of phthisis among Belgian coal miners. Arnold reports that in Germany tuberculous diseases are rare among coal miners and that there is a prevailing opinion that anthracosis is antagonistic to tuberculosis. Goldman attributed the freedom of the coal miner from pulmonary tuberculosis to an antiseptic action of the coal dust.

Other diseases to which coal miners are subject are "beat hand," as a consequence of using the pick and friction of the handle. The skin of the palm over the bases of the fingers of both hands, also the skin

over the fleshy ball of the thumb and that of the other side of the hand, becomes extremely hard and horny. In addition to the enormous thickening of the epithelial layers of the skin there is inflammation of the subcutaneous connective tissue. Occasionally suppuration takes place in the deeper layers of the hard skin. The suppuratory areas are called "keens" by the miners. Beat hand is a painful affection and unfits the individual for work for some time. A similar condition sometimes occurs on the knees and elbows, hence the term "beat knee" and "beat elbow." Miners also frequently complain of backache, largely the result of the peculiar mode of sitting while at work. Dyspepsia, miner's nystagmus, and ankylostomiasis are other conditions to which miners are prone.

**Cancer.**—Chronic irritation produced by coal and petroleum products acts as a chemical irritant in the production of cancer, accounting for chimney sweep's cancer and the tendency to cancer among workers in tar and paraffin, anilin, tobacco, and soot. Arsenic and other irritants are believed to predispose to cancerous growths. See pages 385 and 646.

### EFFECTS OF HEAT

In many trades workmen, more particularly firemen, stokers, workers in foundries and steel mills, are exposed to high degrees of heat. Edsall<sup>34</sup> has recently called attention to the ill effects of exposure to unusual degrees of heat. The symptoms are acute, violent muscle spasms. The acute effect may be heat-stroke and heat prostration; there may be nervous lesions such as focal meningitis, as well as more or less serious circulatory weakness, anemia, acute and chronic disturbances of digestion, acute and chronic nephritis. Respiratory diseases and skin lesions appear to be unduly frequent in persons exposed to high degrees of heat. There is more than a suspicion that cataracts, retinal and choroidal changes, or chronic conjunctival lesions are brought on in glass-blowers and perhaps also in iron puddlers and other persons whose eyes are exposed to very intense heat and light. De Schweinitz states that he can often tell whether men working at puddling furnaces are right-handed or left-handed by studying the effects of this exposure on their eye grounds. Ropke<sup>35</sup> states that Quint described to him cases of right-sided cataract in right-handed iron workers and left-sided in those who were left-handed.

**Unnecessary Noise.**—Unnecessary noise may become a nuisance, and under certain conditions is a menace to health, especially high-pitched sounds long-continued, which lead to deafness; hence the deafness of boiler makers and others is a true occupational disease. Siebenmann and others have demonstrated that long-continued exposure to high-pitched

<sup>34</sup> *Jour. Amer. Med. Assn.*, LI, Dec. 5, 1908, p. 1969.

<sup>35</sup> Weyl's "Handbuch der Arbeiterkrankheiten," 1908.

sounds causes degenerative changes in the organ of Corti in the internal ear.

Noises also disturb rest and sleep, irritate the nervous organism, and induce unpleasant results. The susceptibility to noises varies greatly. Many unnecessary noises can be stopped in shop and street with a corresponding saving of energy and increase of efficiency. It is now realized that unnecessary noise represents misspent energy, and hence so much avoidable waste. Quiet zones at least should be established around schools, hospitals, churches, courts, lecture and music halls, etc.

**Lighting in Industries.**—See pages 916 and 1342.

### COMMUNICABLE INFECTIONS

There are several infections to which workmen in certain industries are specially subjected. Of these the best known are: anthrax, or wool-sorter's disease from hides and hair; and hookworm disease, or miner's anemia, from polluted soil. Also glanders from horses. Tuberculosis sometimes results directly, but more often indirectly, from occupation.

**Wool-sorter's disease** is an infection with *Bacillus anthracis*. The spores cling to the hides of animals that have died from the disease or have been slaughtered on account of it. Spores also remain attached to wool and horsehair and to pig's bristles used in brush-making. The infection may be taken in through the slightest scratch or any open wound or through inhalation of dust containing the spores, or may be ingested in the food. Wool-sorter's disease most often appears in the wool-sorting, wool-combing, and spinning industries, in the manipulation of horsehair for stuffing chairs and mattresses, and the preparation of bristles for brush-making. Anthrax has also been met with in persons employed in tanyards and in warehouses that connect with docks. The subject is fully discussed by Legge in his Milroy lectures.<sup>36</sup>

The prevention of anthrax is first and foremost a problem in animal husbandry which, in this country, comes under the purview of the Bureau of Animal Industry. Animals having anthrax should be killed and all anthrax carcasses should be buried, incinerated, or tanked in such a manner as to destroy the infection and prevent its dissemination. This is one of the questions for international sanitary agreement, for the wool from Prussia, the hair and mohair from Asiatic Turkey, the horsehair from China, the bristles from Siberia, and the hides from India may carry the anthrax spores from these far-off lands and cause infection among our workmen. It is exceedingly difficult to disinfect hides so as to kill the anthrax spores without damaging the hides for commercial use. The methods of disinfecting hides, as well as wool, bristles, hair, etc., are discussed on page 403.

<sup>36</sup> *Lancet*, March 18, 1905.

**Glanders.**—See page 396.

**Hookworm Disease.**—Miners are specially subject to hookworm disease. The parasite enters through the skin from the polluted soil of the mines. The outbreak which called attention to this danger was the epidemic which occurred among the workmen on St. Gothard's tunnel in 1892. Since then the disease has been called "miner's anemia." Gunn<sup>37</sup> found that from 50 to 80 per cent. of those working in the mines of California and the neighboring state of Nevada were infected with hookworms. For a full discussion of hookworm disease see page 153.

**Mouse Favus.**—Mouse favus, or *Favus herpeticus*, in man has recently assumed significance in the United States because of the possibility of those who handle Australian wheat, or who are engaged in milling it, may become infected from the bags, dead mice, or possibly from the wheat itself. Men employed in resacking the grain and women employed in mending the torn and gnawed bags have developed many cases of favus of the glabrous skin. This is the *Favus herpeticus* of Quincke, caused by the dermatophyte *Achorion quinckenium*, which is quite distinct from the typical human favus due to the *Achorion Schoenleinii*. The disease in man develops clinically much as herpes tonsurans. The infection is usually not serious, yielding readily to treatment, and is far more readily cured than favus vulgaris of the scalp.

**Tuberculosis.**—Tuberculosis is often spoken of as the most important disease of occupation. There is no doubt that it is the most important single problem in industrial hygiene, but whether it is commonly contracted as a result of occupation is a question. It is certain that dusty trades, poorly ventilated workrooms, sedentary occupation, fatigue, irritating fumes, long hours and the grind of routine, as well as other factors found in industries, predispose to the disease.

The view generally accepted now is that the infection is usually contracted in infancy or early childhood, but manifests itself clinically later in life. The problem of tuberculosis is intimately bound up with personal habits and home life. Therefore, it is quite as proper to consider it a house disease as an occupational disease. Bad sanitary and hygienic conditions light up latent infections, and it is hopeless to expect arrest or cure of the process so long as the victim continues to work under unfavorable conditions. The problem of what to do for the tuberculous workman and his family, with the "cured" and arrested cases, as well as to find suitable occupation for the pretubercular types, is often a difficult puzzle for the social worker.

Statistics plainly show that tuberculosis, as well as bronchitis, empyema, and other diseases of the respiratory tract, is unusually prevalent among grinders, engravers, compositors, stone workers, millers, bakers,

<sup>37</sup> J. A. M. A., Jan. 28, 1911. Vol. LVI, No. 4, p. 259.

plasterers, brass workers, glass cutters, furriers, weavers, and other trades in which there is undue exposure to dust and irritating vapors.

The subject of tuberculosis is discussed in full on page 163.

Other occupations in which there is a special exposure to the risk of various infections are: physicians, nurses, ward-tenders, pathologists, experimental investigators, etc.

### THE CAISSON DISEASE

The effects of compressed air and the effects of rarefied air are discussed on pages 887 and 890.

## SECTION XIII

### *SCHOOL SANITATION AND PERSONAL HYGIENE*

It took a long time to realize that the whole child goes to school—his body, mind, and soul; that education of the mind alone is one-sided and may be hurtful; finally, that the hygiene of the child and his teacher, as well as the sanitation of school buildings and their equipment, is of fundamental importance. The combination of compulsory education and schools having an unbalanced curriculum or impure water or vitiated air or improper sanitation, is nothing short of a crime by the state against the state. The child profits directly from attendance upon a school which has due regard for the child's physical well being and the development of his character; the state profits indirectly from the lessons in sanitation and hygiene which are carried into the child's home, and are applied as a matter of course in the home of the future citizen. Thus the principles of personal hygiene and sanitation become second nature, and in this way the conquest of the preventable diseases may be materially hastened. It is an economic waste to educate children and then permit them to die of some preventable infection before they have reached the period of maturity and productivity.

The school furnishes abundant material for the physiologist and the psychologist to study growth and development. The effect of the nature and order of the studies for each school year; the hours of work, rest, and play; the direction of physical exercise should all be regulated according to the average requirements and capacities of each school period, and should be based upon accurate observations extending over long periods of time. Both the immediate effects and the remote influences upon adult life should be taken into consideration. Youth is the time of unrest and activity, and it is part of the school work to direct these energies so as to obtain the best development; youth also requires generous nourishment and sufficient sleep. A child who comes to school tired and worn from disturbed slumber cannot profit in body or mind. The child who comes to school hungry or who does not have a judicious luncheon at the recess period is seriously handicapped physically and mentally. The quality of the food offered for sale at recess should be under close scrutiny. The hot lunches and nutritious food furnished some of the school children in Boston, New York and other cities at a reasonable price is a practical and wise movement. See pages 674-676.

One of the duties of the school is to teach and to require at all times cleanliness of person and clothing. The example of clean school-rooms, corridors, lockers, toilets, basement, and grounds will, in time, influence the young citizen. Floors especially should be kept clean and the child be required to use the door mats before entering the building. Dust must be discouraged in all ways. In some schools in poor districts it is a good plan to have shower baths for those pupils who do not enjoy good bathing facilities at home. A toothbrush drill is the means of teaching many a child the first principles in dental prophylaxis. The teacher should be constantly on the lookout to impress upon the pupils the elementary facts in hygiene, such as turning aside the head and holding the handkerchief before the mouth and nose when coughing or sneezing. The teacher should discourage the habit children have of carrying their fingers to their mouths and noses. The anti-spitting rules should be reiterated and strictly enforced. The danger of mouthing toys and pencils and the habit generally of placing things in the mouth should be discouraged; "swapping" partly eaten articles of food should be prohibited, and the reasons explained. Cleanliness is not instinctive in children; it must be learned. The significance of modern biological cleanliness can come only through education and example. Progress in these matters cannot be made without an intelligent understanding on the part of the teacher. It is therefore important to teach the teacher.

Fatigue, prolonged and oft repeated, may injure the development and health of the child. Fatigue is favored by poor ventilation, compulsory sitting upon hard and ill fitting seats at improperly constructed desks, prolonged tension of a strict discipline, studies that are too intensive, and insufficient relaxation or inconsiderate treatment of the little ones. Discipline, obedience, and regard for the human rights of others are among the most important things learned at school.

Many a child is unjustly disciplined and his little soul harassed through no fault of his own, but perhaps on account of defective eyesight or hearing, or some other physical handicap, or as a result of mental deficiency, or even an unusual mental proficiency.

The question of home work should be carefully regulated in accordance with the capacity and age of the child. Children should not be kept busy at prescribed work most of the hours of the day. Some time should be left for quiet play and the encouragement of personal inclinations during which time the best development unconsciously occurs. Initiative, self-reliance, and self-help are submerged by lack of free time. The amount and nature of the work, both in and out of school, must be judiciously considered and should be based upon long years of careful study and observation. The immediate as well as the remote effects should be taken into consideration. Many an ill-tempered child is simply

overwrought and chronically tired out through excessive application of a conscientious and studious nature to tasks beyond the physiological capacity of his little brain and body.

The child should not be sent to school too young. Children must first learn to walk, run, talk, and coördinate muscles before they undertake reading, writing, and arithmetic. Children should rarely be permitted to start school life until they have passed their sixth birthday. Few are sufficiently developed or sturdy enough properly to endure, either mentally or physically, the discipline and exactions of application and study before that age.

Pupils should not be graded according to their ages, but according to their capacity and physical development. Individual aptitudes should be encouraged. The work should be as individual as practicable, and special classes made of backward as well as of forward minds. Special facilities should be afforded for the progress through school of those showing unusual ability.

For the elementary schools one short morning session is enough, but city circumstances often demand two sessions. The general tendency is to reduce the hours of compulsory school attendance and increase the optional time through elective systems which encourage and foster native talents.

Primary pupils should not spend more than one-third of their school time in their seats. Exercises of various kinds that call into play muscular activity are most important at this age, not only for mental growth, but for physical growth, as well as for relief from the fatigue occasioned by sitting at desks.

The child on beginning school life enters an environment radically different from the free and active life which was his before school days began. The effect may be seen by the fact that children usually lose weight and the nervous system becomes affected during the first weeks of school.

The rural school is a problem of magnitude, for 60.7 per cent. of the children of the country are in hamlets and towns of 2,500 and less. Only 18.3 per cent. live in cities of 100,000 and over. The difficulties of the "little red schoolhouse" require special consideration.

Ungraded or special schools should be provided for backward and defective children (page 1349) and for those having favus, ringworm, rachitis, or other conditions requiring either special pedagogical methods or particular medical treatment. Open-air or fresh-air schools for children who have or are threatened with tuberculosis serve a very useful purpose. Ungraded schools for backward and defective children should emphasize vocational training. These children present a serious problem for society. See page 608.

College life is beset with the problems of adolescence—Venus, Bacchus and Mars. The dangers of this age are the venereal peril, tuberculosis, intemperance and drug addiction. The sudden freedom of university life after the strict restraints of preparatory schools is sometimes more than youth is able to withstand.

Finally, the whole school program should demonstrate that the object is not to teach the child to be a child, but to direct his development so as to become a useful man or woman. The school system should therefore be carried out with due regard for future events and should be correlated with the adult life of the child.

**Health Education.**—Health education is fundamental and should be included as part of the required work of all grades. It is comparatively easy to teach and influence children, very difficult to change the habits of adults. All children should learn something about the structure and functions of the body in addition to the principles of hygiene and sanitation. The program of health should make the teaching of health and the prevention of disease an essential part of the education in all schools. It should furthermore seek to improve health and efficiency by practicing the art of hygienic living. It requires constant instruction by example on the part of the teacher in personal hygienic habits and cleanliness. It is necessary to teach the teacher in order that children may receive sound instruction. Teachers, nurses, parents and the children themselves need education concerning adequate nutrition and especially the importance of rest and the evil of chronic fatigue for growing children. The program for health education should cooperate with medical school inspection. Defects which interfere with growth or otherwise handicap children should be removed or corrected.

The best methods are simple and direct. A graded series of textbooks should be used. Interest may be aroused by the picture man, the health fairy, attractive literature, group competition, classroom drills, and above all by the example of the teacher in health habits. In this way advantage is taken of the imitative tendency of children—good example is contagious.

**School Building.**—The school must be centrally located, so as to be convenient especially for the primary and grammar grades, and the school building should be modern, artistic, clean, and sanitary in all its appointments. Every school building should have playgrounds connected with it. Playgrounds should be level and located on the sunny side of buildings; about 30 square feet for each pupil is necessary to meet the demands of play. Thus 1,000 pupils require 300 x 100 square feet for playgrounds alone. In cities, roofs may be utilized for play. A limited play area is best utilized by organizing recess play by sex and grades. School-houses should be built in places that are quiet and free from traffic and nuisances, dangers of various kinds, and on ground

that is either naturally dry or made so by subsoil drainage. The building should be solidly constructed and should stand apart, so that sun and air may reach it from all sides. A substantial and artistic structure well placed has an important influence upon the young mind and character. Trees and judicious landscape gardening should provide shelter and shade and add to the attractiveness. The foliage, however, must not interfere with the light and ventilation of the school-rooms. If the building faces north, with corridors and stairs on this side, all the rooms will have sunlight at some time during the day. The best general arrangement of the plan of the building is that in which the school-rooms are all placed on one side of the building, with the corridors, halls, stairways, and wardrobes on the other. Built in the old way, with rooms around a central well, school-houses have dark central halls and staircases, and favorable lighting cannot be had in some of the school-rooms.

The basement should be under the whole building and carefully protected against dampness. Further, the basement should be well lighted, sunny, and kept clean.

School buildings should have at least two entrances, with doors opening outward; the halls and corridors should be generous and well lighted, and the stairs have easy risers and treads for children. The risers should be about 6 inches and the treads no greater than 12 inches. Inclines may be substituted for stairs.

**The School-room.**—The school-room is the unit in planning a school building; that is, the building should be a number of school-rooms properly disposed, and not a building cut into school-rooms whose size and arrangements are dependent upon the size and shape of the building.

Some of the important considerations in the school-room are the number of pupils to be accommodated, its size and shape, the amount and direction of the light, the ventilation and heating. The three special requisites necessary in all school-rooms are: *adequate air and lighting, proper seating facilities, and suitable books.*

The minimum floor space for each pupil should be 15 square feet. If 18 square feet are allowed all exercises are made easier both for pupil and teacher. Two hundred cubic feet of air space is the minimum commonly allowed; therefore a standard school-room designed to accommodate 30 pupils should be 20 feet wide by 24 feet long, with a ceiling 13 feet high. The best shape for a school-room is that of an oblong, the width being to the length about as 3 to 4. No teacher should be required to have classes exceeding 30 pupils. The rooms, floor space, and air space should be at least as capacious for the primary as for the grammar grades.

## BOSTON STANDARD—ELEMENTARY GRADES

*Size:* 20 ft. by 28 ft. elementary grades.  
 20 ft. by 30 ft. for upper elementary grades.  
 12 ft. high in clear.

About ten or twenty per cent. of rooms should be of a size to seat 50 pupils.

## KINDERGARTEN

800 to 900 sq. ft. and capable of having a circle 16 feet in diameter painted on floor with at least 4 ft. all around it.

## HIGH SCHOOL

26 ft. by 32 ft. for 42 pupils.  
 33 ft. 8 in. by 43 ft. for 60 to 80 pupils.  
 16 ft. by 26 ft. for recitation rooms.  
 3,750 to 4,000 sq. ft. with a height of not less than 24 ft. for high school gymnasium.

The color of the walls should be such as to absorb the least light and prove least taxing to the eyes. A light green-gray is favored for the walls, and white or cream for ceilings. The surface should not be glossy and should either be coated with an oil paint, so that the walls may be washed, or, better, calcimined with a water paint that may be readily renewed. The ceiling should be white, so as to reflect the light.

**The School Furniture.**—The most important articles of school furniture, considered from the view of hygiene, are desks and desk chairs, for the reason that the pupil spends during school hours so much time at work at his desk. Unless, therefore, desks and chairs are constructed with full regard for certain well-known laws of hygiene they produce defects of eyesight, injurious effects as to posture, and wrong habits of carriage which are borne through life and, sadly enough, become more pronounced as the years increase.<sup>1</sup>

Professor Bowditch<sup>2</sup> of Harvard University carefully measured and weighed 25,000 school boys and girls of Boston and found surprising variations. Taking ages on their last birthdays Professor Bowditch found the variations in height indicated in the table on the following page.

Besides the variations in height there is also variation in growth, and provision for this difference must therefore be made in the construction and adjustment of the desk and seat. The growth of girls is more rapid from 12 to 14 years of age, while boys grow most rapidly from 14 to 16 years of age. The annual growth during the maximum period

*Variations in Height of Boys and Girls*

	Boys	Girls
6 years of age.....	47.13 *	47.36
	40.66	40.57
Difference.....	6.47	6.79
11 years of age.....	57.50	57.96
	49.47	49.33
Difference.....	8.03	8.63
15 years of age.....	67.90	65.00
	56.55	57.39
Difference.....	11.35	7.61

\* All figures are inches.

is often an inch more than the annual growth at other periods. Further, there exist certain anatomical differences of proportion between boys and girls. The sitting height of girls is greater proportionately than their standing height in comparison with boys.

*The Desk and Seat.*—The desk and seat must therefore be adjusted so as to provide for differences of height and differences of growth. The desk must not be a prison stall, but should be comfortable and roomy. It must not favor the development of myopia and must not force a pupil into wrong postures. The matter is of greater importance than school men generally recognize.

The chair and seat should be of such a height that the thigh of the pupil when seated will be perfectly level, the lower leg being in an exactly vertical position, with the foot resting wholly upon the floor; that is, the thigh and the lower leg will, when the chair is of a proper height, form a right angle with each other. The seat must therefore be adjusted accordingly. The seat itself should not be flat, but somewhat concave, the lowest part of the concavity being where the tuberosities of the ischium rest. The concavity has the additional advantage of counteracting the tendency to slide forward on the seat when the pupil leans back. The seat should have a back rest that will support the small of the back properly without leaning back excessively. Whether or not it supports the rest of the back is of small consequence. Support of the back carried to the level of the shoulder blades is likely to do more harm than good.

The distance between the seat and the desk should be such that the scholar may read at the desk and write on it without leaning forward more than a little and without entirely losing the support of the back rest. The desk should not be so close as to press against the abdomen, nor near enough to interfere with easy rising from the seat. This

means a distance of  $10\frac{1}{2}$  to  $14\frac{1}{2}$  inches from the edge of the desk to the seat back. It also means that the seat must not project under the desk more than an inch at most. The desk should be high enough for the arm to rest comfortably without much resting on the elbow; not, however, so low that the pupil must bend down to write on it.

If the desk top is made to slide backward and forward it will give the pupil more freedom of movement while at the desk and will also permit him to sit down at the desk and rise from it with greater ease.

FIG. 161.—FAULTY POSTURE. (Shaw's "School Hygiene," Macmillan Co.)

One of the important considerations of a school desk is the proper slope of the top. It is well known that the line of light which least taxes the eyes should fall upon the printed page perpendicularly to its plane. To accomplish this some writers recommend a slope of  $45^\circ$  for the desk top, others  $30^\circ$ . These angles, however, are not practicable. The Vienna Expert School Desk Commission recommends an angle of  $15^\circ$  for the desk top, which is also approved by the experiments of Shaw. Such a slope permits a correct posture in vertical writing.

A foot rest is sometimes attached to desks. The weight of opinion is now against foot rests, as they restrict the free movement of the pupil's feet while at the desk and interfere with opportunity to shift his feet and legs for relief from inactivity, and further interfere with

the thorough cleansing of the floor under the desk. Shaw recommends the Heusinger desk, Fig. 162, and also the Ideal desk. The desk and seat shown in the accompanying photograph, Fig. 163, are known as the Boston school desk and chair. There are now many thousands in use in the Boston schools, and they are being adopted elsewhere.

FIG. 162.—THE HEUSINGER DESK. (Shaw's "School Hygiene," Macmillan Co.)

The seat and chair should be adjusted for each pupil when he enters school or is transferred to another room. Desks and seats should be adjusted at least twice a year: at the opening of school in September and again in February or March.

*The Blackboard.*—The blackboard should be placed upon the wall opposite the principal light. The board should not have a shiny, reflecting surface, and should never be placed between windows or near them.

The best blackboards are made of slate, as they can be washed, which

lessens the dust nuisance. The best slate for this purpose is a greenish or strong black color, which is to be preferred to the grays and brownish-blacks. The loss of light by absorption can be reduced greatly by reducing the blackboard area, and also by covering the blackboard with adjustable curtains. Colored crayons made with arsenic or sulphid of mercury carry danger and should be prohibited. Dustless crayons may now be found on the market.

**Posture.**—Every condition must be eliminated and every care exer-

FIG. 163.—BOSTON SCHOOL DESK AND CHAIR.

cised to prevent the acquiring of physical defects in school, as well as to prevent the accentuation of those physical defects which the child may have possessed before entering school. Posture during sitting is of greater consequence than posture during standing, on account of the longer time the child sits and the muscular fatigue caused by the inactivity of a great number of muscles of the body for a long period. Stooping over the desk leads to myopia; it also contracts the chest and interferes with free respiration, and puts additional labor on the heart; it leads to round shoulders and curving of the spine backward and a carriage in which the head is pitched forward; it also

tends to displacement of the internal organs, both of the abdomen and pelvis.

In order that the pupil may be in a proper physical condition to maintain an erect posture while in his seat, and thus form correct habits which he will carry through life, he must be given periods of relief from sitting at the desk and corrective exercises at different times during the day. In the first year the child should not be confined at his desk more than one-third of the time. In the succeeding years the total amount of time occupied at the desk may be gradually lengthened. In addition to the regular recesses there should be frequent short intervals of respite from sitting at the desk devoted mostly to some form of physical exercise. Vertical writing is conducive to a better position of body and consequent proper separation of eyes from objects regarded than the slanting variety.

**A recess** of not less than 20 minutes during the morning session and again during the afternoon session, when all pupils, if the weather and climate permit, go out of doors and engage in some form of active play,

is of incalculable value in its results upon physical health and mental development. In addition there should be given to each grade every school day at least two short periods of systematic physical drills for pupils and teacher with the windows open.

**Lighting.**—The light must be of proper intensity, equally diffused, and come from the proper direction. So far as intensity is concerned the light must be neither too dim nor too strong, both extremes being harmful. The general rule is that the amount of transparent glass surface admitting light should be from one-sixth to one-fourth of the floor space. The correct amount of window space will depend on the location of the building, direction from which the light is admitted, size and shape of the room, and the proximity of other buildings or objects which might obstruct the light.

The amount of transparent glass surface required for proper illumination must be great enough to afford sufficient light on rainy, overcast, and cloudy days. Excessive window space is scarcely possible, for the excess illumination on bright days may be regulated and softened with shades and awnings.

The amount of illumination is measured by candle meters or candle feet; that is, the illumination afforded by a standard candle at a distance of one meter or one foot. Shaw<sup>3</sup> believes that the illumination should provide at least 50 candle meters in the most unfavorable part of the room.

Factory-ribbed glass or Luxfer prisms disperse the light into the parts of the room where the light is needed, but diminish its total amount; they are of advantage, especially where schools have a small amount of free space in crowded city districts.

The principal light should come from the pupil's left, so as not to throw annoying shadows while writing. Windows may also be placed in the rear of the pupils. When practicable a skylight furnishes the best direction for illumination. Windows may also be placed at the right for ventilating purposes or for admitting direct sunlight while the pupils are not engaged in study. The window sash should be  $3\frac{1}{2}$  or 4 feet from the floor and should reach as near the ceiling as the construction of the building will permit, for the higher the windows reach, the deeper the light penetrates into the room. Light should never enter from the front and shine in the pupil's eyes. Window curtains should be "opaque" and of a greenish cast. The upper fourth of the window furnishes one-third of the light, also the best light, hence it is obvious that curtains should not be hung from the top, but from the bottom, and should roll upward. Artists have long learned the lesson that light from above follows the direction of nature and is most agreeable and best. See *Ocular Hygiene*, page 916.

<sup>3</sup> Shaw, Edward R.: "School Hygiene." The Macmillan Co., N. Y., 1902.

**Ventilation and Heating.**—Ventilation of the school-room is of paramount importance. There is a great waste of time and energy of both the teacher and pupil working in a vitiated atmosphere, for pure air properly conditioned is favorable for good mental work. Bad air means sluggishness, headache, listlessness, inattention, lack of energy, and a depression of mental vigor; further, bad air lowers resistance to certain diseases. In cold climates ventilation and heating go hand in hand.

The first responsibility in a poorly ventilated school room lies with the building committees because of their failure to see that the sum allowed for the ventilating plant is sufficient to give the best that science can devise. The architect often skimps the ventilating system in order to provide a larger and more ornate building.

In favorable climates and during mild weather the windows should be kept open. Even during cold weather the windows should be opened periodically and the room thoroughly flushed out with fresh air. The windows should always be thrown open at recess and also during calisthenic drills and physical exercises and also at the close of sessions. The experience of the open-air and fresh-air schools teaches that cold is a fine tonic for mind and body.

Satisfactory ventilation by means of windows at all times is impossible on account of varying winds, weather conditions, but more especially on account of the impossibility of securing proper attention on the part of the average teacher to the matter of ventilation in addition to other duties. Window ventilation is simplest, cheapest, and all things considered, frequently the best. The Fairchild system of window ventilation is described on page 983.

Every school-room with a proper equipment and a good janitor may be kept well ventilated at all times. Many good ventilating systems are rendered inefficient through the employment of cheap janitors. A good janitor not only means greater efficiency, but a saving in fuel cost.

Direct radiation from stoves or steam coils or hot-water pipes is inadvisable for school-rooms. The hot-air furnace may be used, provided the air is sufficiently moistened, but the direct-indirect system with steam or hot-water pipes is to be preferred. Two thousand cubic feet of air should be provided for each pupil hourly. The Massachusetts law requires 30 cubic feet of pure air every minute per pupil (1,800 cubic feet per hour). The fresh-air inlet should be capacious and separate outlets for the foul air should be provided. The cross-section of inlets and outlets should equal from 16 to 20 square inches for each pupil. Ordinarily it is preferable to place both inlets and outlets on the same side of the room, viz., upon the inner wall or warm side. When so placed the warm air should be admitted about 7 feet above the floor and the foul air should pass out close to the floor.

Special attention should be given to the question of humidity, so that the warmed fresh air shall not be excessively dry.

The temperature commonly accepted as proper for a school-room is between 60° and 68° F. The children would probably work to better advantage if the temperature were kept a few degrees lower and the humidity kept so that the wet bulb never goes above 70° F. (see page 904. A thermometer should hang at about the breathing line in every school-room and the teacher should take hourly readings and keep a record. The temperature of school-rooms is usually too high, and those heated with the hot-air furnace are usually also too dry. Both extremes are prejudicial. If the air of the neighborhood is smoky and dusty it may readily be filtered before it is pumped into the school-room. The combination of the plenum and vacuum systems, the air being driven by rotary fans, is one of the best methods of artificially ventilating school-rooms. (See chapter on Ventilation.)

**Open Air Schools.**—Most children in open air classes gain in weight, color, appetite, attendance, deportment and scholarship. The results are uniformly good and progress in grades is often remarkable, even though the children work little more than half the time. Open air schools must give particular attention to clothing and diet, and also to recreation and rest. The benefits to the subnormal and pretubercular child are proved, and it is difficult to understand why it should not be more widely adapted to the average child. See page 187.

**Water-closets and Urinals.**—Separate accommodations must be provided for the sexes; privies in country districts should be in entirely separate buildings. The urinals should be constantly and automatically flushed and water-closets and urinals should be made to allow complete inspection and use of the scrubbing brush. Thorough ventilation of the toilet-rooms should be planned for and they should be kept clean and sweet at all times. See page 69.

The water-closets may be in the basement if properly constructed and independently ventilated. The floors should be asphalted to facilitate cleaning and flushing, and should be hosed daily, and scrubbed at least once a week. The toilet-room should be well lighted. Deodorizers should not be used, for if toilet-rooms are kept clean and water-closets well flushed they will not be necessary. Urinals should be made of slate or hard asphalt or other non-absorptive material, and one urinal should be provided for each fifteen boys. The out-houses in country schools should be properly constructed and under supervision. In fact, a matron should be in attendance to assist the little tots in the kindergarten and lower elementary grades, and a watchful eye on the part of the master of the school and those he delegates for this duty should be kept to prevent misbehavior in toilet-rooms.

**Cloak-rooms.**—There should be one cloak-room for each class-room, and it should connect both with the hall and the class-room. Cloak-rooms should be lighted from the outside, heated, and thoroughly ventilated to carry off odors and to dry the clothing. Hanging the clothing in the halls is undesirable, for obvious reasons. Each pupil should have a shelf on which to lay hats and small articles, hooks upon which to hang overcoats, and a space for rubber shoes and umbrella.

Teachers should see to it that the pupils do not sit in wet shoes and stockings or in wet clothes. Each school should have some provision for drying wearing apparel, such as a drying chamber which may be in charge of the janitor, to dry the wet clothing during school hours.

Dressing-rooms should also be provided for the teachers. All such rooms and lockers should be kept scrupulously clean.

**Cleanliness.**—Schools should be kept scrupulously clean and every precaution should be taken to prevent dust. Cleanliness of person and surroundings should be one of the most important lessons which the pupil learns at school. Through example and discipline pupils should be taught to love order and neatness and to abhor untidiness and slovenliness. Cleanliness is the keynote of sanitation.

Some of the requirements for schools are: clean drinking water; bubbling fountains and the abolition of the common drinking cup; discontinuance of the roller towel, cake of soap, brush, comb, or other toilet articles used in common; cleanliness of floors, desks, corridors, cloak-rooms, toilet-rooms, basement, and grounds; the prohibition of dry sweeping or dusting. Blackboards should be washed frequently to avoid the dust nuisance, and the floors may be treated with one of the dustless floor oils. The windows should be kept clean, and each child should have his individual books, pencils, and other accessories. Health Day, observed annually, gives a special opportunity to emphasize the importance of hygiene and cleanliness.

**Medical Inspection of Schools.**—The medical inspection of schools is no longer an experiment, but a pressing necessity. It is founded on a recognition of the close connection which exists between the physical and mental condition of children in the whole process of education. It seeks to secure ultimately for every child, normal or defective, conditions of life compatible with that full and effective development of its organic functions, its special senses, and its mental and spiritual powers which constitute a true education.

The object of a medical inspection of schools is not primarily the treatment of diseases, but rather their prevention. One of the principal objects is the early recognition of physical defects such as errors of refraction, imperfect hearing, malformations of the body from abnormal positions, adenoids, enlarged tonsils, and other obstructions of breathing, and sources of inflammation, etc. An important object of the med-

ical inspection of school children is to determine their fitness to enter school and to recognize mental and nervous disorders; also the early recognition of the communicable diseases and measures to prevent their spread; the supervision of vaccination, and disinfection; the teaching of personal hygiene to pupils and teachers, and the sanitation and cleanliness of the school building and its surroundings; the adjustment of the seat and desk, and the medical supervision of the mental and physical work of the child. One of the important functions of medical inspectors of schools is to determine and diagnose the causes of undernutrition. See pages 674-676.

Medical inspection of schools is making slow progress. It is nowhere carried out with the thoroughness and completeness that the subject demands. A systematic school inspection was started in Brussels in 1874 and in Paris in 1884, since which time the movement has become world-wide. In America the first systematic inspection of school children was begun in 1894, after four years' effort by Dr. Samuel H. Durgin, Commissioner of Health of Boston, who is regarded as the father of the system throughout America. The first scientific and extensive examination of school children was made by Dr. Henry P. Bowditch,\* whose essay upon "The Growth of Children Studied by Galton's Method of Percentile Grades" has become a classic in the subject. In 1908 there were only seventy cities outside of Massachusetts having medical inspection of schools. Massachusetts has a compulsory medical inspection law; New Jersey has a permissive one; Vermont has a law requiring an annual testing of the vision and hearing of all school children, and Connecticut one providing for such tests triennially.

Physical defects are not equally significant either from the medical or from the pedagogical standpoint. Each kind of defect should be separately studied, and classification should not include pediculosis with defective vision; club-foot with defective hearing; adenoids with ringworm.

The objects of the medical inspection of schools may be greatly assisted by teaching the teachers the elementary facts concerned.

Medical inspection of schools was organized in this country for the purpose of controlling the communicable diseases of childhood. It must at once be admitted that it has been a failure so far as this object is concerned, for it has had very slight influence upon the prevalence of measles, scarlet fever, diphtheria, whooping-cough, mumps, etc. Theoretically we would expect a good system of medical inspection of school children to check the prevalence of these diseases. Perhaps it does so to a limited extent. With improvements in the system, correlated with child life outside the school, much may still be accomplished along these lines.

\* *Twenty-second Annual Report, State Board of Health of Mass., 1890*, pp. 479-522.

There has been much discussion concerning who shall conduct the medical inspection. It is plain that in any system the teacher must be the ultimate inspector, and teachers are quite competent to carry out simple tests for determining the acuteness of vision and hearing. In one sense the teacher is the foster mother of the child and frequently knows the child better than its own mother. The teacher should report to the medical inspector children who show any of the following symptoms: loss of weight, pallor, puffiness of the face, shortness of breath, swellings in the neck, general lassitude, growing pains, rheumatism, flushing of the face, eruptions of any sort, cold in the head, especially running eyes, irritating discharge from the nose, evidence of sore throat, cough, vomiting, fever or frequent requests to go to the toilet.

The next most important link in the chain of a good system of medical inspection is the nurse. She is able to detect the beginning symptoms of disease and can be trusted to care for simple troubles. The chief value of the school nurse, perhaps, is in establishing communication with the home and securing friendly coöperation with the parents. Parental neglect is rarely due to the lack of parental affection, but to ignorance. The nurse is frequently able to gain the confidence of both child and parent when the medical inspector fails. The nurse, further, will assist the medical staff in carrying out treatment. One of the chief duties of the school nurse is "follow up" social service work.

It is because of the nurse's important place in public health work that it is better to have medical school-inspection, together with its valuable follow-up work, lodged with the health authorities rather than with the educational authorities.

It is the duty of the medical inspector to detect defects, not to treat them. Who shall treat the child is a matter for the parents or guardian to decide. It is not sufficient merely to notify parents that the child needs treatment, for frequently no attention is paid to the notices. The child may be referred to or taken by the school nurse to the hospital or outclinic. In some districts school clinics have been instituted with success.

*Duties of the Medical Inspectors.*—An ideal system of medical inspection of schools would consist of a corps of trained and competent physicians and sanitarians who would devote their entire time to this special work. The staff should have the assistance of experts in ventilation and heating, experts in sanitary architecture, experts in sanitary engineering, and experts in the various medical specialties.

Specialists should visit all school buildings no less than three times each year in order to investigate all matters of heating, lighting, and ventilation, cleanliness, gymnasiums, bath, and toilets, and the seating arrangements with reference to the size of the pupils; the purity of the drinking water, the quality of the food purchased by the children at

the recess period, and the general conditions of the neighborhood that may affect the health of the pupils.

Furthermore, coöperation between the medical and pedagogical departments should be helpful in solving the many difficult problems concerning the curriculum.

In addition to these general inspections all children entering school should be examined medically at least once during each school year. The first examination is for the purpose of establishing whether the child is fit for school and can do the work without injury either to its mental or physical well-being. The second should be a physical examination, which may be made more thorough if the child is required to strip. This, however, should not be done unless the parents of the child are present or give their consent. The third examination consists of special tests of the eyes, ears, nose, throat, teeth, heart, and lungs, weight, growth, nutrition, etc.

Aside from these regular examinations, the school physician must respond to every call when a pupil comes to school having an eruption, fever, or other symptoms indicating a communicable disease. The medical inspector should also oversee disinfection, vaccination, and certify the return to school of any child who has been out of school by reason of a communicable disease.

On account of the tendency for tuberculosis to develop in children who have just suffered from measles, scarlet fever or whooping-cough, as well as to prevent other sequelae of the acute infectious troubles, medical inspectors should be detailed to visit and keep in close touch with such children for from three to six months, or for as long as may be necessary.

**The Communicable Diseases of Childhood.**—Parents naturally come to regard the school as a veritable pesthouse for the spread of the communicable diseases of childhood—especially measles, whooping-cough, mumps, diphtheria, scarlet fever, chicken-pox, common colds, etc. Many of these diseases prevail in epidemic form during the summer time, when school is closed, and under other circumstances which show that epidemics may be independent of school attendance. It is difficult to determine just what part is played by the commingling of the pupils in school in the spread of such diseases and what part is due to other factors. Some diseases take a sudden jump in the autumn with the opening of school. Further, these diseases are not contracted by the school children alone, but are carried home to the other members of the household, and thereby create secondary foci. This problem of the communicable diseases and the schools is far from solution; the spread of these diseases has not been conquered by medical inspection, and their relation to school attendance is one that needs careful observation and study.

A difference is made between exclusion on account of disease and that due to exposure. In the latter case the period of exclusion is based upon the period of incubation of the disease. Immunes are not excluded. Carriers should be looked for.

**Closing Schools on Account of Epidemics.**—The question of closing the schools when some one of these diseases breaks out is often a difficult one to decide. If the children commingle out of school, upon the streets and playgrounds, no useful purpose is accomplished by closing the schools. Hence closing schools is usually more effective in sparsely settled country districts than in cities. Closing schools is economically wasteful and usually has no influence on the course of an outbreak. Children are less apt to infect each other in the class-room than in the home or on the playground. As a rule better results will be achieved by daily inspection of all school children than by closing the schools. At the beginning of an outbreak the schools may be closed for the period of incubation and then opened, but careful guard must be exercised to discover new cases and a watch kept over the return of convalescents. Under these circumstances a daily inspection should be conducted before, and not after, the children enter school. If closing the schools during the period of incubation is not effective nothing will be gained by prolonging the period.

The consensus of opinion now is that the successful control of epidemic disease in school children requires keeping the schools open, with careful daily and frequent periodic inspections; the exclusion of cases and contacts; and home visitation.

A special lookout must be kept for carriers, and laboratory facilities provided to detect the same.

The diseases for which children should be excluded from school are: smallpox, scarlet fever, measles, German measles, chicken-pox, diphtheria, tonsillitis, whooping-cough, pediculosis, mumps, scabies, trachoma, ringworm, impetigo contagiosa, venereal disease, pulmonary tuberculosis, influenza.

**The Eyes.**—Errors of refraction are exceedingly common, and if not corrected may be the cause of headache, nervousness, reflex pains, and a great variety of symptoms. They are also a great handicap to the mental and physical development of the child. The vision of all children should be tested annually, and at least once for color-blindness. It is believed that the unnatural strain of accommodating the eyes to close work (for which they were not intended) leads to myopia in a large proportion of growing children. Thus the percentage of myopia increases markedly from the primary classes through the grammar grades, and is highest in the high-schools. The eyes should therefore be tested and errors of refraction corrected at least once a year. There are certain children who show normal vision by the ordinary tests (Snel-

len test type), yet whose eyes should be examined by an expert if they habitually hold the head too near the book (less than 12 to 14 inches); or if they frequently complain of headache, especially in the latter portion of school hours; or if one eye deviates even temporarily from the normal position. The following symptoms also indicate trouble with the eyes, viz., scowling and wrinkling of the forehead when reading or writing, watery eyes, reddened or granular lids, twitching of the face, inattention, and slowness in book studies in a child otherwise bright.

The conditions which are especially hard upon the eyes are dim light, improper angle of vision, small print, and prolonged focusing at close range. Type for books should not be smaller than the following:

	Type	Width of Leading
First year.....	2.6 mm.	4.5 mm.
Second and third years.....	2.0 mm.	4.0 mm.
Fourth year.....	1.8 mm.	3.6 mm.
Above this grade.....	1.6 mm.	3.0 mm.

In addition to the size the characters should be simple, the ink black, and printed upon paper with unreflecting surface that is free from gloss. Paper of a grayish tone is to be avoided and the paper should be thick enough or of such quality that the print does not show through from the back. Pupils should be taught that it is advisable while reading or during other close focusing of the eyes occasionally to look away and accommodate for distance to relieve the tension and counteract the tendency to myopia. See Ocular Hygiene, page 916.

**The Ears.**—It has been found that approximately 15 per cent. of school children possess some defect of hearing either in one or both ears. Defective hearing is frequently mistaken for inattention upon the part of the pupil, for which he may be unjustly punished. Practical tests to determine the acuteness of hearing should be made separately with each ear by the use of a watch or by the whisper voice. Discharges from the ears, known as abscesses in the ears, or earache should at once be reported to the proper medical attendant.

**Oral Prophylaxis.**—The essential features of oral prophylaxis are (1) normal mucous membranes and associated structures, and (2) cleanliness. The health of the mucous membranes of the mouth and throat, including the closely associated glands and lymphoid tissues and the teeth, depends upon the general health of the body. Cleanliness helps avoid the immediate causes of caries and inflammation.

The *teeth* are living sensitive structures, lying in sockets which resemble a bony joint. The teeth almost always decay from without, as a result of acid formed by bacterial fermentation. Strong teeth in

a healthy body have a much greater power of resisting caries than otherwise. The teeth can even sparkle with the glow of good health. Teeth need exercise by eating the right kind of food in the proper way. A diet of soft, pulpy food weakens the teeth and invites trouble. On the other hand, the public must be taught to have a respect for the teeth, and should know that it is hazardous to use them to take the place of nut crackers or gas pliers.

Caries of the teeth is a disease of civilization. Savages in vigorous health and with nutritious diet do not have decayed teeth, even though they do not use a tooth brush or practice oral prophylaxis. Tooth decay is often an expression of general malnutrition and is frequently associated with enlarged tonsils, adenoids, and other signs of disease or degeneration. In the same sense, "rheumatism" of the joints may not be due to trouble in and about the teeth, for it is often due to the same cause that affects the teeth.

Caries is a decalcification. The common explanation is that the calcium is dissolved by the lactic acid formed by the fermenting food in contact with the teeth. This, however, is not the whole story. It is probable that sound, vigorous teeth have a definite power of resistance and it is now believed that structural changes within the tooth render it susceptible to outside influences. It is quite clear that calcification, as well as decalcification of the tooth, is mainly dependent upon the general nutrition of the body. The ductless glands also influence calcium metabolism. Children need about five times as much calcium in their diet as adults. It would therefore appear that a well balanced diet, rich in vitamins, including whole grains, fresh dairy products and green vegetables, is one of the best preventives against tooth decay. Unbalanced diets, deficient in vitamins, also give rise to conditions of the teeth and gums resembling pyorrhea. "Pyorrhea" may not always be primarily a local infection, but rather the expression of a general condition of malnutrition. One of the early symptoms of scurvy is swelling of the gums, loosening of the teeth and gradual absorption of the cement membrane of the alveolar sockets; in fact, the teeth are among the parts first affected in scurvy.

Some of the accessory causes of dental decay are: low resistance of the teeth because of developmental defects, both antenatal and post-natal; faulty diet both of mother during pregnancy and of the child; neglect of dental attention through ignorance of parents; cost of dental service; lack of dental facilities, especially in rural sections; failure of the child to call attention to the condition of the teeth, either because it is too young or because of fear.

Dental defects influence growth, resistance to communicable infections, preservation of facial symmetry, and degenerative diseases.

From the standpoint of bacteria, the mouth is one of the "filthiest"

parts of the body, and can be kept clean only by special means. For the cleanliness of the teeth, we can well content ourselves with a tooth brush, some silk floss and clean water. In young children, silk floss is not advisable if the space between the teeth is filled with soft tissue. In using silk floss, a rubber band or metal strip, care must be taken not to injure the gums. The teeth can also be polished with a piece of gauze or rubber wrapped about the forefinger. A little soap or some dental powder, free of grittiness, helps to clean the surface of the teeth, and will to some extent help to prevent the accumulation of tartar. Children should be taught the necessity of cleansing all the surfaces of the teeth, and the importance of keeping the tooth brush itself clean by occasional boiling and sunning. A mucin film collects on the teeth which may be precipitated by eating acid fruits. Alkaline mouth washes containing a little bicarbonat  of soda, lime water, or magnesium oxid help correct acid mouths and check the development of "acid spots," discoloration and tartar formation.

Flushing and rinsing the mouth with pure warm water helps mechanically to cleanse the surfaces. Antiseptic mouth washes are a snare and a delusion. It is not possible to add any known germicidal substance to the mouth rinse that will sterilize or disinfect the buccal cavity. The germs are so protected that no disinfectant can reach them, even when applied directly to the infected mucous membrane or gums. Furthermore, any known disinfectant sufficiently powerful to kill bacteria would injure or destroy the delicate tissues and thereby do more harm than good. Many of the mouth washes on the market vary but slightly in their composition from those described in either the Pharmacopoeia or the National Formulary.

The teeth should be examined and cleansed by a competent dentist at least once, and preferably twice, a year. In the light of our present knowledge it is an outrage to allow caries of the teeth to develop into toothache before children are taken to a dentist. Irregularities of the teeth, especially those which make it impossible to close the mouth properly, lead to faulty digestion, to mouth breathing, and other defects. The first permanent molars (6-year molars) are perhaps the most important teeth in the mouth, and are the most frequently neglected because they are so often mistaken for temporary teeth. It should be known that decay of the teeth is favored by the fermentation of starchy foods and sugars, so that an important factor in preventing dental caries is the removal of food particles by frequent brushing and the use of the silk floss. Children should be discouraged from eating crackers and candy between meals and the teeth should be cleaned after each meal.

To provide expert dental attention for all carious teeth, including the temporary set, would overtax the facilities of any community.

Dental hygienists can do much of the cleansing and simpler mechanical work. Dental clinics should be provided in which caries of the temporary teeth should have at least temporary treatment. It should be remembered that one infected tooth is like a rotten apple in a barrel in that it is apt to involve the others.

Streptococcal infections are common about the roots of teeth, especially those that are devitalized or injured. Perhaps the most important structures to maintain the vitality and immunity of the teeth are the pulp cavity and the pericemental membrane. It is also important not to injure the margin of the gums where they join the teeth. Streptococcal inflammations and abscesses frequently form about the roots of such teeth, and sometimes give rise to secondary foci, causing neuralgia, stiff neck, rheumatic inflammation of the joints, sciatica, endocarditis, appendicitis, inflammation of the gall bladder, and other serious complications. These blind abscesses about the teeth should be sought for by radiography and corrected before secondary complications ensue.

All ulcerated, inflamed or diseased conditions in the mouth, including the tonsils, throat, and nose, should be treated without delay and measures taken to prevent their recurrence. Healthy mucous membranes, sound teeth, and normal tissues are our best protection against infection.

**Nose and Throat.**—The noses and throats of all pupils should be examined for any cause of obstruction to respiration, particularly adenoids, polypi, deviation of the septum, etc. Nosebleed should always be reported and inquiry should be made as to mouth-breathing during sleep. In all cases of acute illness the throat and mouth should be examined for indications of scarlet fever or measles and for the signs of tonsillitis or diphtheria, and a culture should be taken in any suspected case of diphtheria. The presence of a discharge from the nose should be noted, and if it is thick and creamy a culture should always be taken. If the discharge from the nose is only from one nostril a foreign body or local cause should be looked for. Adenoids may be inferred from mouth-breathing, snoring, chronic post-nasal catarrh, or recurring ear trouble. Pupils with obviously large tonsils, recurring tonsillitis, and enlargement of the glands of the neck should be referred to a physician for treatment.

**Personal hygiene** deals with much more than the prevention of the communicable diseases. Personal habits may protect the individual against infection, but the problem of preventing the spread of infectious and contagious diseases is largely one of public hygiene. *Personal prophylaxis* is discussed in detail under each communicable disease in other parts of this book.

The chief object of personal hygiene is to live efficiently. The student of preventive medicine is more interested in living well than in

living long. The physical and mental handicaps of life should be corrected; if they are not amenable to treatment, the individual must learn to adjust his activities within the power of his physical machine. This is a problem of compensation. To drive at high speed a machine that is built to go thirty miles an hour invites disaster. This is a problem of personal hygiene—it is individual. It depends first upon a diagnosis of the defect, its nature, its course and its effects; then, an intelligent adjustment to make life satisfactory within the limitations of the body.

Those who are endowed with a robust frame, sturdy physique, sound functions and good constitution must also learn the limits to which the human machine may be driven without permanent harm. One of the important lessons of personal hygiene is to develop good inhibitions, which are fundamental for a temperate, normal life. This is a problem which each person must learn for himself.

Personal hygiene with reference to clothing and exercise will be found in the section on Military Hygiene. Other topics dealing with the subject of personal hygiene are scattered throughout the volume. See Index.

**Diseases of the Skin.**—Apart from the exanthemata the diseases of the skin of school children which are of importance because communicable are: scabies, pediculosis, ringworm, and impetigo.

*Scabies.*—All children who are scratching or have an irritation on the skin should be examined for scabies (the itchmite). It is important that all infected members of the family be treated until cured, else the disease is passed back and forth from one to another. It is also important that all clothing, bedding, towels, etc., and similar things that come in contact with the body be boiled each time they are washed. All cases of scabies should be excluded from school until cured. Sulphur ointment is usually efficacious.

*Pediculi Capitis.*—*Pediculi capitis* (head lice) are extremely common among children, and are communicated directly and also by wearing each other's hats or hanging them on each other's pegs, or from combs and brushes. Every child should have its own brush and comb. These should be cleaned by immersion in boiling water. No person should be blamed for having lice, only for keeping them. The condition may be suspected by the teacher in children who show indications of irritation of the scalp, and the condition is easily detected by looking for the eggs (nits), which are small white objects adhering to the hair. Head lice are best treated by killing the living parasites with crude petroleum and then getting rid of the nits. With boys this is easy; a close haircut is all that is needed. With girls a fine-tooth comb wet in alcohol or vinegar, which dissolves the attachment of the eggs to the hair, may be used. All combs and brushes used should be carefully washed and disinfected.

Children with pediculi should be excluded from school until their heads are clean. See also page 362.

*Ringworm*.—Ringworm of the skin yields readily to treatment, but upon the scalp is usually chronic. When the disease attacks the scalp the hair falls off or breaks off near the scalp, leaving areas the size of a dime or dollar nearly bald. The scalp in these areas is usually dry and somewhat scaly, but may be swollen and crusted. The disease spreads at the circumference of the area and new areas arise from scratching, etc. The diagnosis is made by looking for the fungus.

*Favus*.—Favus is a disease somewhat allied to ringworm, more common in Europe than in America. In this disease quite abundant crusts of a yellowish color are present when the process is active. The roots of the hair are killed by the *Achorion schönleini*, so that loss of hair from this disease is permanent, a scar remaining when the condition is cured.

Children with ringworm or favus should not be allowed to attend school unless the lesions are properly dressed and covered with collodion. Children should be taught to use their own brushes and combs and not to wear each other's hats, caps, etc. In some districts special schools are maintained for favus and for ringworm of the scalp, where the pupils receive treatment.

*Impetigo*.—Impetigo is a disease characterized by pustules which appear on the face, neck, and hands, less often upon the body and scalp. The size of the pustules varies very much and they often run together to form on the face large superficial sores covered with thick, dirty, yellowish, or brownish crusts. The disease is contagious and spreads by scratching as well as by using common towels and other things. Children having impetigo should not be allowed to attend school until all the sores are healed and the skin smooth.

**Nervous Diseases and Mental Defects.**—A sharp lookout for indications of diseases of the nerves and of mental defects should be kept and especial notice taken of suggestive symptoms in a child who did not formerly show them. The teacher should be taught to report instances of restlessness or inability to stand or sit quietly in a previously quiet child, especially if to this are added irritability of temper and loss of self-control, such as crying for trifles or inability to keep the attention fixed.

*Chorea*.—Twitching of the muscles, the result of disease, may cause the child to drop things, render his work awkward, or interfere with writing or drawing. Such children are too often scolded for being inattentive or careless. The indications of chorea (St. Vitus's dance) should not be confounded with habit-spasms such as blinking of the eyelids or the slower twitching movements of the face or shoulders or other parts of the body, which may be due to defects of vision, adenoid

growths, or other reflex causes. Cases of chorea should be removed from school at once, both for the child's safety and to prevent an epidemic of imitative movements such as sometimes occurs. Children with habit-spasms need not be withdrawn from school work, although these conditions often require treatment.

*Epilepsy.*—Mild epileptic attacks (*petit mal*) are frequently overlooked or misunderstood by the teacher. They may be mistaken for fainting. Usually these attacks are only momentary, in which the child stares fixedly and does not reply to questions or in which he suddenly stops speaking or whatever he is doing and is unaware of what is going on about him. The lapse of consciousness is one of the characteristic features of epilepsy. The attack may be accompanied by rolling up of the eyes, drooling, or unusual movements of the lips; an epileptic fit often appears like a choking attack. Teachers very frequently misunderstand epileptic attacks and cannot be expected to distinguish them from hysterical convulsions and other diseases. It does not necessarily follow that cases of epilepsy should be withdrawn from the school, but medical advice should always be had.

*Neurasthenia.*—Neurasthenia or nerve fatigue may be shown by irritability or sleeplessness and other indications threatening a nervous breakdown. This may be due to irregular habits, want of proper sleep, lack of suitable food, poor hygienic conditions, or simply from the child being pushed in school beyond his physical or mental capacity. Excessive fear or morbid ideas, bashfulness, undue sensitiveness, causeless fits of crying, morbid introspection, and self-consciousness may also be symptoms of a neurasthenic condition, and call for investigation and for the teacher's sympathy and winning of the child's confidence to prevent developments of a more serious nature. Excitability is often the first stage of fatigue and is frequently mistaken for brightness and therefore encouraged.

The teacher should know that forgetfulness, loss of interest in work and play, desire for solitude, untidiness in dress or person, and like changes of character are sometimes incidental to the period of puberty.

*Defectives.*—Mentally defective children in the public schools exhibit certain common characteristics which soon become evident. The typical incorrigible child of the primary grades often is a mentally defective child of the excitable type. They are destructive, cruel to smaller children, and often precocious sexually. Certain cases show marked moral deficiency. Mentally defective children must be distinguished from those who are only temporarily backward as a result of some removable cause such as defective vision, impaired hearing, adenoid growths, or as a result of unhappy home conditions, irregular habits, want of proper sleep, lack of suitable food, bad hygienic conditions, etc. Teachers should refer to the medical inspectors for examination children

who, without obvious cause, such as absence or ill health, show themselves unable to keep up in their school work, who are unable to fix their attention, or are incorrigible.

A careful lookout should be kept for children showing sexual perversion, for one sexual pervert may demoralize a whole school.

**Vaccination.**—Vaccination should be required of all children before they are permitted to attend school. The evidence of a successful vaccination usually accepted is a physician's certificate or a characteristic scar. For the indices of a successful take see page 12. School children should be vaccinated before entering school and again before entering high school.

## SECTION XIV

### DISINFECTION

#### CHAPTER I

##### GENERAL CONSIDERATIONS

**Disinfection.**—Disinfection means the *destruction of the agents causing infection*. An object is said to be infected when contaminated with pathogenic microorganisms. It is disinfected by destroying these organisms, whether they are in the substance or on the surface of that object. Disinfection, then, deals only with destroying the vitality of those minute forms of life which cause disease. It does not mean the destruction of all the lower forms of animal and vegetable life that may be in or upon an object—this is sterilization. See Concurrent and Terminal Disinfection, page 1357.

Disinfecting procedures properly applied have an important part in the prevention of communicable diseases. Their efficiency decreases as the distance between the place of origin of the infection (the patient) and the point of their application is increased.

**Sterilization.**—*Sterilization means the destruction of all microbial life on or in an object.* A sterile object is a lifeless object. All processes which sterilize necessarily disinfect, but all disinfecting processes by no means sterilize. The distinction between disinfection and sterilization arises principally from the fact that spores have a much greater resistance to all influences which destroy the vegetative cells. Fortunately, none of the pestilential diseases of man which occur in widespread epidemics, so far as known, are caused by microorganisms with resistant spores; therefore the usual processes of disinfection may be thoroughly efficient, yet leave many harmless and hardy forms of microscopic life alive. In other words, sterilization is rarely necessary in public health work, except in the case of anthrax, tetanus and other spore-bearing infections such as malignant edema and the gas bacillus group.

**Antiseptics.**—Antiseptic substances *prevent decomposition and decay*. Such substances retard or prevent the growth and activity of microorganisms, but do not necessarily destroy them; that is, antiseptics delay or prevent fermentation and putrefaction without destroying the micro-

organisms which cause the processes. There is a great difference between the antiseptic and the disinfecting power of most substances. For instance, a solution of formalin will restrain the development of most bacteria in the proportion of 1 to 50,000, but it requires a 3 to 10 per cent. solution of this liquid to kill the bacteria in a reasonably short time. As weak a solution of bichlorid of mercury as 1 to 300,000 will sometimes prevent the germination of anthrax spores, whereas it requires a 1 to 1,000 solution to destroy them. Saturated solutions of salt or sugar will preserve meat, vegetables, and other organic substances; that is, they are antiseptic in their action but not germicidal, as they have small powers of destroying microorganisms. Cold is also antiseptic or preservative in action, not germicidal.

**Asepsis.**—Asepsis means *freedom from or absence of living pathogenic microorganisms*. Surgical asepsis may be achieved through physical cleanliness without the use of active germicidal substances.

**Germicide.**—A germicide is *a substance or agent which destroys germs*. Germicides and disinfectants are interchangeable terms, as both are used to indicate the destruction of microorganisms. Many germicides used in public health work are potent enough to sterilize objects with which they come in contact.

**Deodorant.**—A deodorant is *a substance which has the power to destroy or to neutralize unpleasant odors*, such as those arising from organic matter undergoing fermentation or putrefaction. Such substances must be distinguished carefully from disinfectants. Deodorants destroy smells; disinfectants destroy germs. Many of the disinfecting agents are also deodorants, but all deodorizing substances are by no means disinfectants. For example, charcoal will absorb the malodorous gases arising from putrefying and fermenting materials, but it is inert so far as its power to destroy the cause of these processes is concerned. Formalin and ozone, on the other hand, are true deodorants and disinfectants, as they combine with the organic matter to form new compounds which are both odorless and sterile. Bichlorid of mercury, while a very potent germicide, has practically no immediate effect upon odors. The volatile oils and other substances having a pungent odor are not deodorants, they simply cover up one smell with another.

**Fumigation.**—Fumigation consists in *liberating fumes or gases with the object of destroying germs, vermin, insects, rats, mice and other small animals acting as carriers of infection*. The chief fumigants used in public health work are formaldehyd and sulphur dioxid; to a less extent carbon monoxid, funnel gases, hydrocyanic acid, pyrethrum, carbon bisulphid, chlorin, etc. Most of these are very poisonous to higher forms of life, but have little or no germicidal power—excepting formaldehyd which is a good germicide, but feeble insecticide. Fumigation cannot take the place of disinfection; gases at best have but the merest surface

action. As they lack the power of penetration they cannot be depended upon to disinfect even thin fabrics, or surfaces soiled with sputum or similar discharges in which the virus is protected against the fumigating gas.

Fumigation is chiefly useful in preventing the spread of insect-borne diseases.

The terms fumigation and disinfection have been much confused. Because *fumigation* is not necessary or ineffective after some of the communicable diseases—the word has gone forth that *disinfection* is unnecessary and useless. No mistake could be greater. Fumigation has its place and its limitations in public health work—so also disinfection.

**Nature's Disinfecting Agencies.**—In nature many forces are constantly at work to destroy infection and thereby limit the spread of the communicable diseases. It is the duty of the sanitarian to encourage the use of these natural disinfecting processes: they are dilution, sunlight, dryness, time and antibiosis. Sunlight is a great destroyer of germ life. Few microbes, especially the pathogenic ones, can live in the direct bright sunlight many hours. Dryness is another natural condition that is destructive to many of the minute forms of life with which we have to contend. The combination of dryness and sunlight is quite as good, if not better, than the ordinary fumigating processes which are commonly used in practical disinfection against surface contamination. Dryness, sunlight, and cleanliness are the keynotes of sanitation in the modern acceptance of the term.

We now know that most of the pathogenic microorganisms do not grow and multiply in our environment. For the most part they soon die when wafted into the air, deposited on surfaces, conveyed in water or placed in the soil. It is only occasionally that some of them find conditions favorable for development in foods such as milk and meat, and exceptionally in water. Further, it is to be noted that ordinarily it requires a certain number of microorganisms to produce infection. It is quite likely that a single typhoid bacillus or a single tetanus spore may "kindle a conflagration," but experimental evidence with the infections upon laboratory animals teaches the lesson that ordinarily an animal is capable of taking care of minute amounts of infection, particularly if attenuated. It requires at least ten tubercle bacilli to cause tuberculosis in a guinea-pig. Dilution, attenuation, and the conditions of our environment, unfavorable to most germs harmful to man, therefore protect us in no small measure against the communicable diseases. This is one reason why so many of the communicable infections are contracted largely through close personal association.

**Cleanliness.**—Cleanliness is a very important adjunct to the work of disinfection. In fact, cleanliness lies at the base of all our sanitary measures. The mere act of cleaning removes some of the adherent microbes

from the surface and the ordinary scrubbing and washing result in the final destruction of many more. Dry dusting and sweeping serve only to stir up dust and infection, which settle down again upon the same or other surfaces. Cleanliness serves another important purpose, so far as infection is concerned; it removes the organic matter on which and in which bacteria may find favorable conditions for prolonging life and virulence. The modern conception of cleanliness has expanded with the growth of the sanitary sciences. We now aim at biological cleanliness as well as esthetic cleanliness. This includes not only the removal of organic matter, but the destruction of insects and vermin, and their feeding and breeding places (see page 1006). So far as personal cleanliness is concerned, the two important acts to prevent infection are: (1) Washing the hands before eating, before handling food and after leaving the toilet; and (2) keeping the fingers away from the mouth and nose.

The surfaces frequently used or handled by the public, such as wood-work, seats, floors, desks, door handles and the like in schools, stores, factories, shops and public conveyances and assembly places should, when practicable, be frequently scrubbed with hot soap-suds and strong soda solution. This also includes the seats of water-closets and privies, wash-basins, and other objects used in common.

In the wholesale disinfection which must be practiced to check widespread epidemic diseases due to bacterial infection we are largely limited to the use of the agents which nature has constantly at work to destroy such infection. Against a single case of communicable disease or against a limited infected area we may employ aggressive measures such as steam and strong chemicals; but when a disease, due to bacterial infection, has spread over an extensive district these methods must be supplemented by all the resources of nature. The people must be educated so as individually to employ intelligent measures to avoid the infection. Cleanliness must be more scrupulously practiced than ever, sunlight and dryness must be given their fullest opportunity to operate even at the expense of a few faded carpets or colors.

**Antibiosis and Symbiosis.**—Many pathogenic microorganisms are destroyed in the process of putrefaction and fermentation. They die in the fierce struggle for existence going on in the process of decomposition. For the most part the hardier saprophytic forms of life overpower and kill the disease-producing microorganisms which have comparatively feeble powers of resistance. The fact that infected carcasses, sewage, and putrid organic matter generally purify themselves by the very processes that destroy them is a fortunate provision of nature.

Ordinarily, only one major infection is active in the same individual at one time. Symbiosis is noted in the case of tetanus, which is favored by other microorganisms. Influenza and measles invite infection with

the pneumococcus and predispose to tuberculosis. On the other hand, there are curious instances of antibiosis, thus sarcoma may disappear after erysipelas.

**When and Where to Disinfect.**—It naturally suggests itself that it is much better to prevent infection than to be compelled to destroy it after it has become disseminated through ignorance, carelessness, or negligence. It is the duty of the disinfecter to destroy infection wherever it is found; it is the ideal of the sanitarian to prevent the spread of infection so as to render broadcast disinfection unnecessary.

The best place to apply disinfection is at the seat of origin of the infection. Man is the fountain-head of most of the infections to which he is heir; hence the *most effective place to practice disinfection is at the bedside*. The excretions, especially those from the mouth, nose, and bowels, as well as discharges from eruptions and wounds most frequently need attention. When proper precautionary measures have been taken at the bedside with a case of cholera, typhoid fever, or diphtheria there is little need of subsequently disinfecting the sickroom, but when a diffusion of the infection results then a general disinfection becomes necessary.

**Qualifications of the Disinfecter.**—The disinfection of any given place is a complex operation, and should not be attempted by anyone not familiar with the peculiarities of the particular infection with which he has to deal and a thorough knowledge of the disinfecting agents employed. In other words, it is quite as important to know *what* to disinfect as *how* to disinfect and *when* to disinfect. A thorough understanding of the causes and modes of transmission of the communicable diseases is the most useful weapon the disinfecter has in his fight against the spread of infection.

The success of the disinfecter lies in personal attention to minute details. Germs are little things, and it is little things that count in this kind of work. The disinfecter who is satisfied to leave the process in the hands of an inexperienced person with a few words of instruction cannot expect to obtain trustworthy results. The disinfecter must give personal surveillance to the whole process—the materials, the strength of solutions, modes of application—and must be present to guide and direct every step of the operation with the same conscientiousness and thoroughness with which the surgeon assures himself of every detail of asepsis in his operating clinic.

Much of the routine disinfection done by departments of health is probably ineffective, although the procedure is faithfully carried out as a routine. The average fumigating squad does not understand the effect of temperature, humidity, outside winds, porosity of walls, shape and size of enclosures, and the rate of application and other factors of the gases employed.

**Controls.**—Disinfecting processes should be controlled by exposing cultures upon paper slips or threads as a guide and check to the thoroughness of the process. To control gaseous disinfection, saturate threads with an active culture of *B. prodigiosus*. These threads are attached to little slips of paper which are then exposed in various portions of the room to be treated. After the completion of the operation the threads are inoculated into Dunham's peptone medium. If the *B. prodigiosus* has survived the characteristic red color appears in the culture medium. Suitable control exposures should also be used from time to time with steam disinfectors and other apparatus.

**Disinfection Must Be in Excess of Requirements.**—The disinfection of rooms, bedding, ships, and objects that have been exposed to infection must of necessity be greatly in excess of the actual requirements. This is one of the difficulties met with in attacking an invisible foe. A sick-room might readily be disinfected and rendered safe by applying a few gills of one of the germicidal solutions to a small spot or a limited area. But, as we cannot see the germs, it is necessary to apply our disinfecting agents to every inch of surface of the room and all its contents in order not to miss that particular spot. At first disinfection was directed by a shotgun process in a general sort of blunderbuss way against everything, but now that we know more about the habits and habitat of each one of the particular microorganisms we can concentrate our efforts with some exactness upon the particular objects liable to transmit infection, and with greater assurance of eradicating danger.

**Specificity of Germicides.**—There are few universal poisons and few if any general germicides. Most disinfecting substances are more or less specific in action. Germicidal agents often show marked selective action towards bacteria, spirochetes, protozoa, algae or the "ultra microscopic" viruses. Thus, phenol and the cresols have comparatively feeble action against the virus of smallpox, vaccinia, and other filterable viruses. Copper sulphate is a specific poison against algae. Sodium oleate favors the growth of gram negative cocci of the *Micrococcus catarrhalis* group and of staphylococci, while pneumococci and streptococci of the hemolytic and *S. viridans* variety fail to develop.<sup>1</sup> Fuchsin (Endo's medium) suppresses *B. coli*, but does not inhibit *B. typhosus*. Glycerin kills non-spore-bearing bacteria, but preserves filterable viruses. Gentian violet and other para-rosanilin dyes kill gram positive, but not gram negative microorganisms. Bile salts dissolve pneumococci and restrain the growth of staphylococci and streptococci, but favor the growth of typhoid and colon bacilli. Ethylhydrocuprein is specific for the pneumococcus. Acridin with mercuric chlorid has remarkable properties of penetrating tissues. There are many other examples of selective action. Hence, the killing of *B. typhosus* or any other test organism is not a proof of gen-

<sup>1</sup>J. A. M. A., Dec. 21, 1918, Vol. LXXI, p. 1050.

eral disinfecting power. There is a tendency towards the development of specific germicidal agents.

**Chemotherapy.**—Most cells of the body are more easily killed than bacteria. All the ordinary germicides used in public health work are quite destructive, even corrosive to the tissues of the body. Since Ehrlich found that "606" (salvarsan) will kill spirochetes without serious injury to the body, the search has been to find specific substances that will kill the parasites without harming the host.

**The Ideal Disinfectant.**—The ideal disinfectant must first and foremost possess a high germicidal power. It must not be rendered ineffective by the presence of organic matter; it must be reasonably stable, so as not to deteriorate under ordinary conditions; it must be soluble or readily miscible in water; if it forms an emulsion the emulsion should be permanent; it should be harmless to man and the higher animals; it should have the power of penetration; it should not corrode metals, bleach, rot or stain fabrics, and, finally, it should be reasonable in price.

The stress of modern activities demands disinfecting processes that are instantaneous in their action, all-pervading in their effects, cheap, harmless, and free from unpleasant odors that might be offensive to the fastidious. Such perfect disinfectants are not known. It requires money and the expenditure of well-directed and intelligent energy to accomplish satisfactory disinfection. *No one substance is applicable to all diseases or to all substances, or even to the same disease or the same substance under different conditions.*

**Concurrent disinfection** signifies the immediate disinfection and disposal of all infected material during the course of the illness. It implies the prompt disinfection or destruction of all infected discharges and of all articles soiled by them. Furthermore, it includes the purification and cleanliness of the immediate environment of the patient so as to check the spread of infection.

**Terminal disinfection** signifies the precautions taken to destroy or purify infectious material after the removal of the patient or the termination of isolation or quarantine, the object being to destroy infection or to kill the insects or animal carriers of disease. *Terminal fumigation* finds its chief usefulness in fighting the insect-borne diseases.

*The distinction between fumigation and disinfection* must be kept clearly in mind (page 1352). Terminal fumigation for measles and certain frail and short-lived viruses is not necessary. Furthermore, gases such as formaldehyd are uncertain in practice, and have the merest surface action. Both concurrent and terminal disinfection of discharges and objects likely to convey infection will always remain an important measure of prevention.

*Terminal fumigation* during recent years has been disparaged as a public health measure because it has little effect upon the control of the

communicable diseases and the cost of such "disinfection" appears to be disproportionately large to the benefits. The evident limitations of terminal fumigation have cast doubt in the minds of some health officers upon the value of disinfection in general. This is an unfortunate attitude. No one can question the great value of disinfection properly applied. It is, of course, much more important to destroy the infective discharges throughout the course of a case of typhoid fever than to trust to one final disinfection of the sick-room and its contents. The same holds with about equal force for most of the communicable diseases. We now know that fomites play a comparatively minor rôle in the transmission of disease. The disinfection of rooms and objects does not now, therefore, hold the importance in the minds of sanitarians that it once did. However, if terminal disinfection prevents the occurrence of only a small number of cases it would still seem to be worth while. Moreover, what health officer would willingly allow his child to occupy the bed or handle the objects in a room soon after a case of typhoid, scarlet fever, tuberculosis, or diphtheria without first applying some effective method of purification? The greater the care and cleanliness exercised during the progress of the disease the less the need of terminal disinfection. A good cleansing of surfaces with soap and water, followed by an application of bichlorid, carbolic acid, or one of the cresol preparations is a more effective method of disinfection than formaldehyd gas, which is the best of the gaseous agents. Cleansing, renovating, airing and sunning of the room should always be the final process.

The principal *objects that need disinfection* are the discharges from the body; towels, bedding, handkerchiefs and fabrics; food, tableware and other objects that have been mouthed, and finally the hands of the nurse, physician and others who come in contact with the infection.

**Penetration.**—In practical disinfection a certain amount of penetration is almost always called for. Most germicides penetrate poorly and slowly. As a rule, substances in solution penetrate better than substances in emulsion. Gaseous substances cannot be depended upon to penetrate at all. They have only the merest surface action. Feces and sputum are not only the most difficult to penetrate, but also the most important because so apt to contain virulent pathogenic microorganisms throughout their mass. No germicidal agent can be depended upon to permeate a fecal mass under ordinary conditions in a reasonable time. It is, therefore, most important that such substances be thoroughly disintegrated and the germicide incorporated through the mass. Bacteria in nature are usually imbedded in various substances which differ greatly in consistency and composition, and therefore practical disinfection calls for stronger solutions and longer time than indicated by laboratory tests upon the naked germ cells. In certain instances, where penetration is required, trust should only be placed in steam, dry heat, or

boiling. Dry heat has poor powers of penetration compared with steam. The penetration of steam and of gases is facilitated by a prior vacuum. None of the ordinary chemicals can be trusted to penetrate upholstered furniture, mattresses, pillows, thick blankets and the like.

**Organic Matter.**—Organic matter seriously interferes with the efficiency of almost all germicidal agents. Chlorinated lime, ozone, hydrogen peroxid, potassium permanganate, and other active oxidizing agents attack organic matter with avidity and are thus soon used up. The metallic salts coagulate organic matter, thus automatically impeding further ingress. Formaldehyd and phenol show less reduction of power in the presence of organic matter than perhaps any of the other germicides.

In nature, bacteria are usually imbedded in organic matter. The way in which organic matter handicaps germicidal action has been shown by many investigators. Behring found, for example, that anthrax bacilli suspended in water are killed in a few minutes with bichlorid of mercury 1-500,000; in bouillon it required 1-40,000; while in blood serum 1-2,000 was not always effective.

**Time.**—Time is an essential factor too frequently disregarded in disinfecting with liquids—suspension or solution. Very few chemical disinfectants act instantly, even in strong solutions, and under favorable conditions. The microorganisms are so often in clusters or are surrounded by mucoid films or are so imbedded in organic matter that a considerable time is required for the disinfecting solution to penetrate to the germ. If the microbes are dry it takes a certain time to wet them before the chemical can act. These and other factors must be added to the time actually necessary for the substance to destroy the life of the germ after it comes in direct contact with it.

It is well-known that some germicides, particularly the metallic salts, if given sufficient time, will eventually kill in exceedingly weak dilutions. Mercuric chlorid, according to Chick and Martin, will act as a germicide in a dilution of 1 to 1,000,000 if given sufficient time. The action of copper sulphate in exceedingly weak dilutions on algae is also of interest in this connection. Some disinfectants, on the other hand, exert their most useful action promptly, and are then rapidly used up by being oxidized or neutralized and thus lose their power.

Chick found a logarithmic ratio between concentration of disinfectant and the time taken to disinfect. She found, furthermore, that the phenol coefficient of mercuric chlorid with *B. typhosus* varies greatly with the prolongation of exposure. Thus:

Phenol coefficient of HgCl <sub>2</sub>	2.5 minutes exposure =	13.5 coefficient.
" " " " 10	" " =	175 "
" " " " 30	" " =	550 "

This is an interesting side light on the Rideal-Walker technic which, until recently, permitted a latitude of time of comparison varying from

2½ to 15 minutes. This wide variation of the coefficient, however, is found mainly in the case of the metallic salts.

Time is an exceedingly important element in disinfection. It is not sufficient simply to dip the hands in and out of a bichlorid solution, to rinse fabrics in carbolic acid solution, or to pour formalin over feces. It takes time to penetrate and then to kill. Further, the speed of the reaction varies with each substance, and depends upon the concentration and also the temperature.

**Speed of Disinfection and Stability of Disinfectants.**—A knowledge of the speed with which a disinfectant acts is essential to an understanding of the conditions under which it may be used to best advantage. The speed of disinfection is an important factor, for it varies enormously with different types of substances. Germicides of the chlorin group and iodine are among the most rapid, while dyes and some metallic salts are relatively slow. As a general rule, germicides that act promptly are quickly decomposed or neutralized. Stable germicides act slowly, unstable germicides act quickly. A list of germicides with reference to these factors follows:

#### INORGANIC DISINFECTANTS

Hydrogen peroxid and some of its derivatives.	Unstable, easily decomposed during disinfection.
Chlorin.	Unstable, easily decomposed during disinfection.
Hypochlorous acid and its salts.	Unstable, easily decomposed during disinfection.
Bromine and iodine.	Less unstable than chlorin.
Boric acid and its salts	Stable.
Mercury salts.	Often inactivated by precipitation or otherwise.
Bismuth salts.	Often inactivated by precipitation or otherwise.
Zinc salts.	Often inactivated by precipitation or otherwise.

#### ORGANIC DISINFECTANTS

Alcohol, ether, etc.	Stable.
Iodoform	Fairly stable.
Formaldehyd	Unstable.
Hexamethylenetetramine and its derivatives.	Mostly stable.
Aromatic chloramines.	Unstable, easily decomposed during disinfection.
Phenols, naphthols and derivatives.	Mostly stable.
Dyes, such as malachite green, acriflavine, etc.	Mostly stable, though sometimes reduced to leuco-forms and often adsorbed by tissues.

**Temperature.**—There is a complete analogy existing between a chemical reaction and disinfection, one reagent being represented by the disinfectant and the other by the protoplasm of the bacterium. Chick states

that the velocity of disinfection increases with the rise in temperature in a manner similar to that of a chemical reaction. In fact, the temperature so greatly influences the disinfecting power of liquids that it is strongly recommended always to use warm solutions in actual practice. Even slight changes of temperature may make a great difference. Feeble antiseptic solutions become strong germicides when warmed. Phelps claims that as the temperature increases arithmetically, the velocity of reaction increases geometrically. This is not a general rule applicable for all disinfectants, for Chick showed that the germicidal power of the metallic salts increases 2 to 4 fold for each rise of  $10^{\circ}$  C., while phenol usually rises 7 to 8 fold for each similar change in temperature.

A good instance of the effect of temperature is given by Heiden, who found that anthrax spores which survived the effects of a 5 per cent. carbolic solution for 36 days at room temperature were destroyed in half an hour in the same solution at  $55^{\circ}$  C. At  $75^{\circ}$  C. it took only 3 minutes to kill them. A 3 per cent. carbolic acid solution killed the same spores at this temperature in 15 minutes and a 1 per cent. solution in from 2 to  $2\frac{1}{2}$  hours.

It is important to remember that *the temperature registered by the thermometer of the apparatus is rarely a true index of the temperature of the things to be disinfected*. This is a common source of error in the use of autoclaves and sterilizers where large objects or masses are heated, such as cans of food, bundles of bandage, bales of fabric, or quantities of clothing. The temperature recorded on the thermometer of the sterilizer is usually higher than the actual temperature within the apparatus. Good sterilizing technic is essential and a factor of safety desirable. The time necessary for penetration must be taken into account.

The critical temperature in the center of bales, bags, cans, etc., can be determined with the thermo-couple or special recording thermometers. In the use of steam under pressure, the temperature is a more reliable guide than the pressure.

**Emulsions and Solutions.**—As a rule an emulsion has greater germicidal power than a solution. Thus soapy and resinous emulsions of the phenols may accentuate the germicidal power of these substances. Chick and Martin have observed that the particles of an emulsion or soapy preparation of the coal-tar acids exhibit active Brownian motion. The bacteria are considerably larger than the mean diameter of the emulsified particles. The bacteria may plainly be seen to be bombarded by these particles. In this way the bacteria are frequently brought into intimate contact with the undiluted particles of pure coal-tar acids. The maximum effect may therefore be obtained and the death of the bacteria is inevitable. Such concentration about the bacteria is not likely to occur with substances in solution. The coal-tar acids in suspension act

upon the bacteria first through adsorption, and then through chemical combination. The bacteria rapidly become surrounded by the disinfectant in a much greater concentration than actually exists within the liquid. Other particular matters present have the same power of adsorption, and their presence therefore interferes with the germicidal value of substances in emulsion. Thus the value of phenol in solution is barely impaired by the presence of organic matter while emulsified disinfectants are reduced to one-third or one-half their original value. That germicidal substances in emulsion fail to penetrate may be demonstrated by pouring one of the coal-tar emulsions upon a fecal mass; a layer of the coal-tar creosotes soon collects upon the surface, plainly visible as a film.

**Dilution.**—There must be a sufficient amount of the substance used so that it shall be present throughout the whole mass in the proportion required. Thus an agent that is effective in a 2 per cent. solution cannot be used in that strength to disinfect an equal volume of an infected liquid, since the mixture would then contain but 1 per cent. This is particularly important in the disinfection of urine, feces, sputum, vomitus and the like.

**Reaction.**—Some germicides are acid, others alkaline; the substances to be disinfected also vary in reaction. Thus lime is an alkali, and if used to disinfect an acid substance enough must first be added to neutralize the medium and then an additional amount of lime must be added necessary to accomplish the disinfection. In the same way, if mercuric chlorid is added to solutions containing sulphids, caustic alkalies, or certain metallic salts, sufficient must be added in order to first precipitate these substances and then enough more added to exert its disinfecting action. Likewise, the greater the number of germs to be destroyed the greater the amount of the disinfectant required to accomplish the purpose.

**The Mechanism of Bactericidal Action.**—Chemical substances and physical agents act in a great variety of ways to bring about the destruction of bacteria. Just how the microbes are poisoned is, in many instances, an unsolved problem in toxicology. It must be self-evident that disinfectants act in different ways, especially when we consider such widely diverse substances as acids, metallic salts, phenols, ozone, bleaching powder, and chloroform.

Kronig and Paul,<sup>2</sup> as early as 1897, established the important known facts in a classic contribution. They showed that the toxicity of the metallic salts depends upon:

- (1) The concentration of the metallic salt.
- (2) The specific property of the salt.

<sup>2</sup> *Zeitschr. f. Hyg.*, 25, p. 1, 1897.

- (3) The type of solvent.
- (4) The degree of dissociation of the salt.
- (5) The effect of the cation.
- (6) The effect of the anion.
- (7) The effect of the undissociated salt.

With regard to the acids, the toxicity depends upon:

(8) The electrolytic dissociation, that is, the concentration of hydrogen ions in solution. In a few instances, the anions have a specific toxic effect.

The toxicity of the bases is in accordance with:

(9) Their dissociation power, that is, with the concentration of hydrogen ions in solution.

The disinfecting power of the halogens:

- (10) Increase with their atomic weight.

The oxidizing chemicals are toxic:

- (11) In proportion to their oxidizing power.

With regard to negative and positive catalysis, they found that:

(12) Anything that will increase the dissociation will increase the toxicity.

(13) The alcohols are positive catalyzers when acting on the metallic salts, and negative catalyzers when in solution of phenol and formaldehyd.

(14) Bouillon, gelatine and the body fluids are negative catalyzers in metallic salt solutions.

Krönig and Paul recognized the probability of the existence of certain general arbitrary laws between the concentration and toxicity of the metallic salts.

In 1908, Chick,<sup>3</sup> using the figures obtained by Krönig and Paul in 1897, and those later obtained by Madsen and Nyman<sup>4</sup> in 1907, and supplementing these results with a number of her own obtained with anthrax spores, was able to show a close similarity between the process of killing and the equation for a unimolecular reaction embodying Guldberg and Waage's law. Her experiments with *B. paratyphosus* showed a departure from this simple law which she explained as due to permanent differences in resistance to disinfectants among individual organisms.

In 1918, Brooks,<sup>5</sup> using the rate of hemolysis of blood cells, con-

<sup>3</sup>*Journ. of Hyg.*, 8, p. 92, 1908; also 10, p. 238, 1910.

<sup>4</sup>*Zeitschr. f. Hyg.*, 57, p. 388, 1907.

<sup>5</sup>*Journ. Gen. Physiology*, Sept. 20, 1918. I, No. 1, p. 61.

cluded that disinfectants do not follow the unimolecular law. He believes that the fundamental reaction may be either a simple process or the expression of a complex series of changes, whose rate is at all times governed by that of the slowest of the series.

The conception that disinfection resembles a chemical reaction, the disinfectant representing one reagent and the bacterium the other, is of great importance since the *cardinal points of efficient disinfection*, namely, *adequate active mass*, or concentration of the germicide, *time of action*, and *perfect contact* are thereby experimentally established.

**The Choice of Germicide.**—The choice of the germicide depends somewhat on the nature of the substance to be disinfected, as well as upon the resistance of the virus. Ordinarily germicidal solutions, such as bichlorid of mercury, 1-1,000, or carbolic acid, 2½ per cent., cannot be trusted to kill tetanus spores; emulsions are not serviceable for the disinfection of feces; a weak chlorinated lime will disinfect water, but a strong solution is necessary to disinfect fabrics, but the strong solution bleaches and rots the fiber. Certain chemicals have a selective action and appear to be specific poisons for some organisms as, for example, copper sulphate for algae. On the other hand, carbolic acid is particularly ineffective against the virus of smallpox. Taken altogether, therefore, the choice of the chemical, its strength, and time of application, the temperature of the solution, and its method of employment, are all problems which must be solved for each particular class of infection, and each particular group of substances.

## THE STANDARDIZATION OF DISINFECTANTS

There is no accurate standard by which the power of disinfecting agents may be measured. There are conditions influencing the life of the bacterial cell which we are unable to control. It is for this reason that the strengths of solutions necessary to disinfect are variously stated by different authorities, and the time of exposure is for the same reason not always definitely decided. The difficulty in this connection is to determine the minimum conditions which will furnish trustworthy results and still provide a coefficient of safety necessary for general practice. Of still greater importance is the fact that our laboratory tests do not imitate the natural conditions under which bacteria are commonly found in nature. The requirements of practical disinfection are therefore usually much more severe than the conditions of our laboratory tests.

While the results of scientific work in the laboratory must be our guide as to the value and efficiency of any disinfecting process we cannot ignore the results of experience gained in actual practice in combating the communicable diseases. This is especially true of disinfectants

used against a disease the cause of which is only surmised or the mode of transmission not definitely known. We have had a lesson on this point in the case of sulphur. This substance had long been used as a disinfectant for yellow fever, and practical experience had justified the confidence placed in sulphur fumigation to check the spread of this disease, but when the scientific tests made in the laboratory showed that sulphur dioxid is a very poor germicide, discredit was thrown upon it; now that we know that sulphur dioxid is one of the best insecticides, confidence has been restored both as to the scientific and practical value of this substance.

On the other hand, laboratory experiments have established with great accuracy the value and reliability of certain disinfectants which otherwise would have been overlooked. Thus the value of corrosive sublimate, chlorinated lime and formaldehyd was established, while on the other hand some substances, such as zinc chlorid and sulphate of iron, have been robbed of the high place in which they were formerly held, and placed near the bottom of the list of disinfectants. Even carbo-lic acid has been shown to have less germicidal power than was formerly supposed.

**Methods of Standardizing Disinfectants.**—Pringle<sup>6</sup> as early as 1750 attempted to standardize the then known antiseptics by determining their power to preserve (i. e., prevent decomposition in) a mixture consisting of 2 grains of meat and 60 grains of sea salt in 2 ounces of water. Following Pringle's work little was accomplished for over 100 years in standardizing disinfectants until Koch started a new era by the use of pure cultures and the "thread method."

*The Thread Method.*—Koch<sup>7</sup> in 1881 used pure cultures of *B. prodigiosus*, *B. pyocyaneus*, and *B. anthracis*, both with and without spores. He soaked threads in a culture of the test organism and afterward dried them for various periods and then exposed these infected threads to the action of the disinfectant to be tested. The threads were then washed and laid on the surface of a solid nutrient medium and incubated for growth. This method, although characterized by greater scientific accuracy than the methods previously used, lacked perhaps those broader features of the older, rougher experiments; that is, the method did not approximate the conditions met with in practical disinfection closely enough. Koch's reports, so favorable to bichlorid of mercury, gave a great impetus to its use. Geppert,<sup>8</sup> however, soon made it plain that Koch's high regard for bichlorid of mercury was partly due to an overestimate of its destroying power, inasmuch as the thread may

<sup>6</sup> *Phil. Trans. of the Roy. Soc. of London*, XLVI, 525.

<sup>8</sup> "Mitteilungen aus dem kaiserlichen Gesundheitsamte," I, 1881, p. 324, abstracted by Whitelegge, in "Recent Essays," New Sydenham Society, London, 1886, CXV, p. 493.

carry over a sufficient amount of the chemical to inhibit growth. Gelpert used ammonium sulphid to precipitate the mercury and thereby demonstrated a lower figure as to its germicidal power.

*Sternberg's Method.*<sup>9</sup>—As early as 1881 Sternberg described a method that is evidently the precursor of the "carbolic coefficient" and its various modifications. He mixed 5 c. c. of a young culture with equal quantities of a solution of the germicidal agent. Thus 5 c. c. of a 1 to 200 solution of carbolic acid would be added to 5 c. c. of a recent culture of typhoid, and after stated intervals 1 or 2 loopfuls would be transferred to a nutrient medium.

*The Garnet Method.*—The Garnet method proposed by Krönig and Paul<sup>10</sup> in 1897 was an attempt at a more precise method. Small garnets of uniform size are coated with an emulsion containing sporulating anthrax bacilli. These are dried and then dropped into the disinfecting solution. After exposure for stated intervals the garnets are removed, rinsed, and the organisms washed off in sterile water, plated, and counted. Krönig and Paul emphasized the necessity of the disinfectant reaching each organism, the subsequent washing of the disinfectant from each organism, and the performance of the test with a constant number of organisms, since the time required for disinfection is dependent upon the number of microorganisms present. This method, along with the thread method of Koch, has been supplanted by the "carbolic coefficient" of Rideal and Walker and modifications thereof.

**Carbolic Coefficient.**—Rideal and Walker<sup>11</sup> in 1903 introduced a method by which they proposed to determine and state in definite numerical terms the value of any disinfectant. This they called the "carbolic coefficient," for the reason that carbolic acid is taken as the unit of measurement against which the germicidal power of all other substances is compared. It is often spoken of as the "Rideal-Walker" method or the "drop" method, because one drop of the culture of *B. typhosus* was used for each c. c. of disinfectant tested.

Rideal and Walker opened a new era in the standardization of disinfectants. They prepared a number of standard conditions for the test, without which comparable results are not possible. The most important conditions are temperature, media, nature and age of the test microorganisms, time of exposure, degree of dilution, etc. The Lancet Commission<sup>12</sup> in 1908 recommended several modifications of the Rideal-

<sup>12</sup> "The Standardization of Disinfectants," *Lancet*, 1909, II, 1454, 1516, and 1612.

Walker technic and this method was further modified by Anderson and McClintic<sup>13</sup> who, in 1911, proposed certain changes in technic, and a different method of calculating the coefficient, which they termed the "phenol coefficient." Stimson<sup>14</sup> described a machine by which the testing may be facilitated.

Kendall and Edwards<sup>15</sup> in 1911 described an infected agar plug, designed to test the penetrating power of a disinfectant.

*Physical-Chemical Methods.*—It remains to cite the admirable work of Chick and Martin<sup>16</sup> upon the laws of disinfection. They proposed in 1908 that the time element be established arbitrarily and with this called for two other constants, namely, the number of bacteria initially present, and the temperature. They believed that the killing of bacteria simulates a monomolecular reaction in which the bacteria take the place of one of the reacting substances. Phelps<sup>17</sup> in 1911 made the interesting proposal to determine the germicidal value of a disinfectant at any temperature and concentration by a mathematical formula which would use the findings of a single experiment of comparatively easy technic.

**Carbolic Coefficient Method.**—This test, sometimes known as the Rideal-Walker method of standardizing disinfectants, has been variously modified and improved.<sup>18</sup> As modified it is at present the best method we have for comparing the strengths of germicidal substances in solution or suspension. The method, however, has distinct limitations, as it only gives information concerning the relative value of germicides upon the naked germ cells under comparatively favorable conditions of action.

In order to obtain results that may have comparative value and to avoid discrepancies it is of the greatest importance to keep all the factors of the test uniform and to give attention to every detail. The following are the more important factors and principles upon which this test is based:

*Time.*—The time is taken as the constant and the strength of the disinfectant as the variant. It is easy to demonstrate that, if reversed, totally erroneous results will be obtained.

The carbolic coefficient above described is not the Rideal-Walker Technic but modified in part from the Hygienic Laboratory Phenol Coefficient, and in part from the Lancet Commission Method.

*Test Organism.*—The coefficient will vary with different microorganisms. The culture recommended is a 24-hour-old *B. typhosus* grown in bouillon. It is important always to use the same strain of typhoid, as

FIG. 164.—DEVICE FOR DETERMINING CARBOLIC COEFFICIENTS.

Consists of a wooden box 14" long by 14" wide by 15" high, containing a metal pail (A) 10" in diameter, and 8¼" deep. A shelf made of wire mesh (B) is inserted 2" from the top of the pail, which is filled with water. A pipe with a faucet (C) from the bottom of the pail will be found very convenient to draw off the water and regulate its temperature. Asbestos packing (E) completely surrounds the pail in order to insulate it. The lid of the box (F), which is raised in the drawing, contains openings for the five test-tubes, and three other openings for cultures and thermometer. When the lid is in place the test-tubes rest upon the shelf (B). A drawer (D) in the bottom of the box is convenient to keep test-tubes, inoculating needles, thermometer, and other parts of the apparatus.

different races vary in resistance. Further, the culture should be carried over every twenty-four hours on at least three, preferably seven successive days before using it in a test. It is advisable to filter the culture

through filter-paper in order to remove clumps just before beginning a test. The culture should always be grown under the same conditions, upon the same medium, so as to insure uniformity.

*Medium.*—The standard beef-extract broth (reaction  $+1.0$ ) recommended by the Committee on Standards of the American Public Health Association for Water Analysis, is used both to grow the test typhoid organism and also for the sub-cultures made after exposure to the disinfectant. Ten c. c. of this broth are placed in each test-tube for the sub-cultures, as this amount is sufficient to avoid any antiseptic activity of the disinfectant carried over.<sup>19</sup>

*Phenol*, first proposed by Rideal and Walker, and now adopted by common consent, is the standard of comparison. Phenol may readily be obtained chemically pure, and exact solutions may be prepared by titration with bromin. A 5 per cent. stock solution is usually made and this is diluted for the purpose of the test. Another advantage of phenol is that it is relatively unaffected by the presence of organic matter. Only formalin perhaps is superior to it in this regard.

*Temperature of Exposure.*—This is one of the most important factors. The germicidal activity of substances increases with the temperature. In this respect germicidal reactions resemble chemical reactions. It is therefore of the utmost importance that the solutions tested should be always at the same temperature, and for this purpose 20° C. has been selected as most convenient. The solutions to be tested and the typhoid culture itself must be brought to this temperature before they are mixed, and then maintained at this temperature in a water-bath.

*Proportion of Culture to Disinfectant.*—Rideal and Walker first proposed to use one drop of the typhoid culture to each cubic centimeter of germicidal solution. It is more accurate to use a measured amount, say 0.1 c. c. of the 24-hour-old bouillon culture of typhoid to 5 c. c. of solution. These are convenient amounts easily and accurately measured with standardized delivery pipets. It should be kept in mind that the addition of the bouillon culture dilutes the germicidal solutions, but as this is a constant factor it does not affect the comparative values as expressed by the carbolic coefficient, but may be taken into consideration in judging the germicidal values for practical work.

*Inoculation Loops.*—Precisely the same quantity of fluid from the mixture should be removed each time for the transplants. This is done most readily with platinum loops made of 23 U. S. standard gauge wire and a loop 4 millimeters in diameter inside measurement. This may be made over a No. 14 wire U. S. gauge. Several of these loops should be on hand. They are sterilized and placed upon a rack. As one is used it is flamed and returned to the rack, so that it will be cool when taken in its turn.

<sup>19</sup> See Modification of Media. U. S. Pub. Health Rpts., Oct. 17, 1919, p. 2297.

**Dilutions.**—A standard series of dilutions should be made of the phenol standard and also of the germicide to be tested—in accordance with the tables in Hygienic Laboratory Bulletin No. 82.

**Technic.**—The following method is the one used in my laboratory for carrying out the carbolic coefficient:

A solution of 5 per cent. phenol c. p. is made and standardized chemically.<sup>20</sup> The usual dilutions of 1 to 90, 1 to 100, and 1 to 110, etc., are made from this stock solution as desired.

The solutions of the germicidal substances to be tested must be made accurately, according to volumetric or gravimetric methods.

The tests are carried out in test-tubes one inch in diameter and three inches long. These are placed in a row in a water-bath. The test-tubes

FIG. 165.—ARRANGEMENT OF TUBES IN WATER-BATH AND THEIR CONTENTS.

rest upon a bed of sand and are held in place by a wire rack or simply by a board perforated with holes of suitable size. If the water-bath is sufficiently large and the water brought to just 20° C. it may be maintained at this temperature with but slight attention.

Each test-tube receives 5 c. c. of the solution to be tested. Time is allowed for the solutions to reach the temperature of 20° C., then the culture which has previously been brought to 20° C. is added and mixed with the solution in each test tube in turn. The culture is added to each tube at intervals of just 30 seconds. With a row of five tubes this will make a 2½-minute interval for each tube as the subsequent sub-inoculations are made.

Two and one-half minutes after the phenol and the culture have been mixed together in tube No. 1 a loopful of the mixture is removed and planted in broth; 30 seconds later a loopful of the mixture is taken from tube No. 2, and so on throughout the series at intervals of 30 seconds. The entire procedure of removing the loopful of mixture and planting it into one of the test-tubes containing 10 c. c. of broth requires only about 15 seconds, allowing plenty of time to flame the loop, replace it in the rack, and pick up another loop which had previously been flamed

<sup>20</sup> By bromin titration. (See description in Sutton's "Volumetric Analysis.")

and has cooled sufficiently for the next operation. The test-tubes holding the mixture of germicidal solution and culture need not be removed from the water-bath, and it is not necessary to keep them plugged with cotton. The loop should always be plunged to the bottom and care taken not to touch the sides of the test-tube and always to carry away a loopful of the fluid to be transplanted. The test-tubes holding the medium for the transplants are conveniently placed in wooden racks and are incubated at 37° C. for forty-eight hours, when the readings as to growth (+) or no growth (—) are tabulated.

An example of a carbolic coefficient test follows:

		2½ Minutes	5 Minutes	7½ Minutes	10 Minutes	12½ Minutes
Phenol	1 : 90 .....	—	—	—	—	—
Phenol	1 : 100 .....	+	—	—	—	—
Solution X	1 : 900 .....	—	—	—	—	—
Solution X	1 : 1,000 .....	+	—	—	—	—
Solution X	1 : 1,200 .....	+	+	+	+	+

The carbolic coefficient of solution X is therefore  $\frac{1000}{100} = 10$ .

The carbolic coefficient is determined by comparing the strengths of the unknown disinfectant with phenol that "show life" in 2½ minutes—or practically the strengths that kill in 5 minutes. Previously it was permissible to compute the coefficient upon any of the periods of the test up to 30 minutes. However, it was found possible in this way, either by chance or intent, to obtain an extravagantly high coefficient. Thus Chick and Martin showed that the phenol coefficient of certain metallic salts varies from 13.8 to 550, depending on whether the period of comparison is 2½ or 30 minutes.

Anderson and McClintic<sup>21</sup> have modified the procedure employed by the Lancet Commission to determine the coefficient to be the mean between the strength and the time coefficient; that is, the figure representing the degree of dilution of the weakest strength of the disinfectant that kills within 2½ minutes is divided by the figure representing the degree of dilution of the weakest strength of the phenol control that kills within the same time. The same calculation is done for the weakest strength that kills in 15 minutes. The mean of the two is the coefficient.

An example of the "phenol coefficient" as determined by the Hygienic Laboratory method is given on the next page.

Kendall and Edwards<sup>22</sup> have devised an ingenious method to determine the penetrating power of germicides in the presence of organic matter. The method consists essentially of cylindrical molds of agar

impregnated with the test organism. Sections of these cylindrical molds or "artificial feces" are exposed to the germicide solutions and plants made after proper intervals of time from a core taken from the center of the cylinder.

*The carbolic coefficient of any substance should be based upon the average of a large number of tests.*

**Interpretation of Results.**—A low carbolic coefficient usually means a useless disinfectant. Formalin has a low coefficient, although formaldehyd is one of our potent and serviceable germicides. The reason for this discrepancy consists in the fact that the coefficient is based upon formalin which contains only 40 per cent. or less of formaldehyd. On the other hand it should be remembered that because a germicide has a high coefficient is no true indication that it is a favorable agent in practical work. There are many factors still to be considered. Thus a useful disinfectant should not be very poisonous to higher animals; should not corrode metals or rot fabrics; should not stain or bleach; should not have an unpleasant smell; should be reasonably cheap; should be readily miscible with water and not deposit from solution or suspension; should be reasonably stable; should act both in alkaline and acid media; should not be greatly influenced by the presence of organic matter, and should possess a fair power of penetration. Further, it should not be specific, but be a general poison for all microscopic plant and animal life. It must at once be evident that no one test can determine all

† The following disinfectants have a coefficient of less than 1. Most of them are so weak that it was impracticable to determine the coefficient.

of these factors, so that a thorough and comprehensive study of the substance to be used should be made upon many different parasites under many different conditions before we can have a satisfactory knowledge of its power and limitations. This is one of the reasons that makes us conservative about taking up new germicidal substances until thoroughly tested under different conditions, *and inclines us to adhere to well-known chemicals such as bichlorid of mercury, carbolic acid, the coal-tar creosotes, lime, the hypochlorites, and formalin, the advantages and limitations of which have been thoroughly established.*

## CHAPTER II

### PHYSICAL AGENTS OF DISINFECTION

**Sunlight.**—Sunlight is an active germicide. It destroys spores as well as bacteria. Unfortunately, the sunlight is so uncertain and the force of the sun's rays so variable and their disinfecting powers so superficial that it cannot be depended upon as an aggressive measure in attacking infection. In rooms, ships, and confined spaces sunshine comes more under the purview of the sanitarian than under that of the disinfecter, but the latter can always use it to advantage in supplementing his other methods. Rooms and objects should always be sunned and aired after disinfection.

The different rays of light have very different effect upon germ life. The blue-violet and ultraviolets, that is, the more refrangible chemical rays of short wave length, are the only ones possessing germicidal power. The red and yellow rays are practically inert in this regard. The source of light seems to have little influence upon the result; it is more a question of intensity and nature of the rays. Even diffused light retards growth and development of bacteria, and if strong enough will finally kill them. Electric light containing the proper rays is efficient. The Röntgen rays have no bactericidal properties. The sun is the natural generator of ultraviolet rays.

The time required for sunlight to destroy bacteria varies with its brightness and with conditions such as moisture, temperature, transparency, and composition of the media, which aid or hinder the effect of the rays. The time also varies with the different microorganisms; plague bacilli and cholera vibrio usually die more quickly than tubercle bacilli. Spores are much more resistant to the influence of the chemical rays than the bacterial cells themselves. Thus it usually requires about thirty hours' sunning to kill an anthrax spore, while the anthrax bacillus is killed in one or two hours when subjected to the same conditions.

**Ultraviolet Rays.**—Ultraviolet rays are invisible rays which lie beyond the violet end of the spectrum. In general it may be said that they include those rays of short wave lengths between 2,900 and 2,250 Angstrom.<sup>1</sup>

The wave lengths of the visible spectrum are from about 7,610 Ang-

<sup>1</sup> One Angstrom unit is 1/10,000,000 of a centimeter.

strom units (red) to about 3,970 (violet). According to Nogier<sup>2</sup> the ordinary ultraviolet rays extend from 3,920, to 3,000 units, the average rays from 3,000 to 2,200, and the extreme ultraviolet rays from 2,200 to 1,000 units. He states that rays from 3,920 to 3,000 are not bactericidal to any extent but produce sunburn after long exposure. Rays between 3,000 to 2,200 have a strong action on bacteria while those from 2,200 to 1,000 are still more powerful but are of little value since they are easily absorbed by air and other substances.

Ultraviolet rays from the Cooper Hewitt lamp, produced by an electric discharge through mercury vapor contained in a quartz lamp in vacuo, have an exceedingly powerful germicidal action, killing spores as well as bacterial cells. Glass is opaque to these rays of short wave lengths and it is therefore necessary to use quartz globes.

Cernovodeanu and Henri<sup>3</sup> have shown that the action of ultraviolet light is greater near the lamp and decreases as the square of the distance from the source of the rays. Ultraviolet rays act just as well at 0° C. as at 55° C. They also act equally quickly in the presence or absence of oxygen. Pure cultures of non-spore-bearing microorganisms are killed in from 5 to 60 seconds. Molds, however, are only partially destroyed.

Ultraviolet light does not act indirectly through production of hydrogen peroxid or ozone, but kills bacteria by some direct action upon the protein which it seems to coagulate and decompose.

On the whole, very satisfactory results have been obtained in disinfecting clear water with ultraviolet rays, and in several cities in France and elsewhere the municipal water supply is treated by this process. See pages 916 and 1144. Proteins and other bodies of high molecular weight interfere with the action of the rays. Turbidity, both organic and inorganic, has a similar action. Color, within certain limits, seems to have no influence whatsoever.

Ultraviolet rays cannot be used successfully to pasteurize milk for the reason that milk is opaque, and furthermore the rays act upon the protein, causing unpleasant odors and tastes to develop. Attempts to kill the bacteria in turbid water, beer, wine, and vinegar have been only partially successful, because the organic matter interferes with the penetration of the rays.

Ultraviolet light possesses no therapeutic value so far as direct destruction of bacteria within any of the tissues of the body is concerned. Verhoeff<sup>4</sup> has shown that ultraviolet light will not destroy bacteria

<sup>2</sup>Nogier, T.: "Les Rayons ultraviolets et leur application à la stérilisation des liquides," *Rev. d'Hyg. et de Police Sanit.*, T. 32, 1910, pp. 421-431.

within the cornea, even when the latter is perfectly transparent, without at the same time severely injuring the corneal tissues. See also page 918.

**Electricity.**—It appears that electric currents have little germicidal action in themselves and that the apparent effects noted by some investigators are due either to the heat generated by the current or to electrolytic action. Electricity has very little use in practice as a disinfectant. Hermite used the products of electrolysis for the sterilization of sewage. He added sea-water to the sewage and the electrolytic action caused the formation of hypochlorite, which has well-known germicidal action. The effect of electrical currents upon bacteria seems to be a purely chemical one in the case of germicidal substances being formed by electrolytic decomposition; or a thermal one in the case of the production of heat, which so frequently attends the discharge of electric currents.

**Pressure.**—Hite<sup>5</sup> finds that a pressure of 100,000 pounds per square inch, at room temperature, destroys most non-spore-bearing bacteria. Under these conditions, milk containing from 30 to 40 million per c. c. may be reduced to a few hundred by the application of 100,000 pounds for 10 minutes. The pressure does not affect the enzymes. Forty-five thousand pounds pressure is sufficient to kill *B. typhosus* in beef broth in 10 minutes. *B. diphtheriae* in beef broth are killed at 40,000 pounds pressure in 10 minutes.

Larson, Hartzell and Diehl<sup>6</sup> found that a direct pressure of 6,000 atmospheres kills non-spore-forming bacteria in 14 hours. A pressure of about 12,000 atmospheres for the same length of time is required to kill spores. Non-spore-bearing bacteria are killed by CO<sub>2</sub> of 50 atmospheres pressure in about 1½ hours. Yeast cells withstand the action of CO<sub>2</sub> for more than 24 hours, probably because of their ability to transmit the CO<sub>2</sub> molecule through the membrane promptly. Nitrogen under a pressure of 120 atmospheres has no effect on bacteria.

**Burning.**—Fire is the great purifier. Burning has, however, a very limited range of usefulness in practical disinfection. The disinfectors is seldom justified in burning an article against the wish of its owner, for we now possess methods by which any object may be rendered safe so far as its power of conveying disease is concerned. In actual practice, however, the disinfectors often comes across a great amount of rubbish and articles of little value that he will find easier and cheaper to burn than to disinfect. The burning of garbage and refuse is the safest means of disposing of such organic substances from a sanitary standpoint, especially in districts where pestilential disease prevails. From the same standpoint the cremation of all bodies dead of a communicable

<sup>5</sup> *Bull. 146*, W. Va. Agricul. Exp. Sta., October, 1914.

<sup>6</sup> *Journ. Infect. Dis.*, March, 1918, p. 271.

disease is the safest method of preventing possible spread of infection from this source. Burning is the most satisfactory method of disinfecting and disposing of small amounts of sputum and other infected discharges. Burning of the surface of the ground by means of gasoline torches and petroleum is sometimes used to destroy animal parasites and other infections which find lodgment on the soil. The gasoline torch is also used to fight insect pests of trees and plants.

**Dry Heat.**—A temperature of 150° C. continued for one hour will destroy all forms of life, even the most resistant spores. It is easy to maintain this temperature in an apparatus of special construction known as a hot-air or dry-wall sterilizer. Dry heat penetrates slowly, especially through fabrics. Air is also a poor conductor. It must therefore be remembered that the temperature as registered on the thermometer does not necessarily indicate the temperature at the critical place within the sterilizer. A liberal factor of safety is therefore necessary, especially in large scale operations. In the sterilization of glassware and other objects in laboratories making biologic products, it is customary to expose them for at least two hours to not less than 170° C. to insure penetration and heating of all surfaces. Glassware and many other objects will stand this degree of heat and are sterilized in an oven of this kind in bacteriological laboratories and in surgical clinics.

Dry heat is not as satisfactory a disinfectant as moist heat, as it lacks the power of penetration and is injurious to fabrics. Most materials will bear a temperature of 110° C. without much injury, but when this temperature is exceeded signs of damage soon begin to show.

Scorching occurs sooner with woolen materials, such as flannels and blankets, than with cotton and linen. Over-drying renders most fabrics very brittle, but this injury may be lessened by allowing the materials which have been subjected to dry heat to remain in the air long enough to regain their natural degree of moisture and pliability before manipulating them.

The ordinary household cooking oven is as good as any specially contrived apparatus for the disinfection of small objects by dry heat. In the absence of a thermometer it is usual to heat the oven to a point necessary to brown cotton and expose the objects no less than one hour.

**Boiling.**—Boiling is such a commonplace, every-day procedure that it is often neglected in practical disinfection despite the fact that it is one of the readiest and most effective methods of destroying infections of all kinds. An exposure to boiling water at 100° C. continued for an hour will destroy the living principles of practically all the infectious diseases with which we have to deal in public health work. To be sure, there are a few spores that have shown a remarkable resistance to boiling water and streaming steam in laboratory experiments. Boiling, there-

fore, cannot be entirely depended upon where tetanus, anthrax, or resisting spores are in question. As a matter of fact, a degree of moist heat much lower than the boiling point of water is effective against the great majority of the known viruses. Thus a temperature of 60° C. for 20 minutes will destroy the microorganisms of cholera, typhoid, dysentery, diphtheria, plague, tuberculosis, pneumonia, erysipelas, and practically all non-spore-bearing bacteria. Boiling kills them at once.

Boiling is especially applicable to the disinfection of bedding, body linen, towels, and fabrics of many kinds; also kitchen and tableware, cuspidors, urinals, and a great variety of objects. Surfaces, such as floors, walls, beds, metal works, etc., may be effectively disinfected by mechanically cleansing them with boiling water. The efficacy of boiling water, especially when used in such circumstances, is greatly increased by the addition of corrosive sublimate, carbolic acid, or one of the alkaline coal-tar creosotes. The addition of lye, borax, or a strong alkaline soap also increases the penetrating and detergent power of boiling water when applied to surfaces soiled with organic or oily matters.

Boiling in 3 to 5 per cent. phenol or some similar disinfectant will kill tetanus and other spores. This method is applicable to rubber goods and other articles.

In using boiling water for the disinfection of bright steel objects or cutting instruments the addition of 1 per cent. of an alkaline substance such as carbonate of soda will prevent rusting and injury to the cutting edge. The method advocated by Rebula<sup>7</sup> is as follows: Two and one-half grams of sodium hydroxid (NaOH) should be added to 1,000 grams of water. The sodium hydroxid should be allowed two minutes in which to dissolve and to combine with the CO<sub>2</sub> of the water before the instruments are put in the solution and boiled.

**Steam.**—Steam is one of the most satisfactory disinfecting agents we possess. It is reliable, quick, and may be depended upon to penetrate deeply. Further, it does more than disinfect; it sterilizes. Vegetating bacteria are killed instantly and most spores in a short time. It may therefore be used to destroy the infection of any of the communicable diseases.

Either streaming steam or steam under pressure is used in practical disinfection.

Streaming steam has the same disinfecting power as boiling water, and an exposure of half an hour to an hour is sufficient. Steam under pressure is a more powerful germicide than streaming steam. At a pressure of 15 pounds<sup>8</sup> to the square inch steam has a temperature of approx-

<sup>7</sup> *Centralblatt f. Chirurgie*, Oct. 16, 1920, 47, No. 42, p. 1297.

<sup>8</sup> That is, 15 pounds above atmospheric pressure. Barometric pressure is zero. Throughout this book, "pounds pressure" means "gauge pressure."

imately 120° C. and may be depended upon to sterilize in 20 minutes. At 20 pounds pressure it has a temperature of approximately 125° C. and will sterilize in 15 minutes. The following table gives the temperature at various pressures and vice versa.

Temperature		Pressure		
Degrees C.	Degrees F.	Mm. of Mercury	Pounds per Square Inch	Gauge Pressure *
100	212	760.00	14.70	0.0
105	221	906.41	17.53	2.83
110	230	1075.37	20.80	6.10
115	239	1269.41	24.55	9.85
120	248	1491.28	28.85	14.15
125	257	1743.88	33.72	19.02

\* That is, pounds per square inch above atmospheric pressure.

The *temperature* is a much more reliable guide than the *pressure*. The temperature of the *object* to be disinfected, rather than the temperature of the *apparatus* is the critical factor. Many failures are due to neglect of this simple point in physics.

Penetration may be greatly facilitated by a partial vacuum before introducing the steam.

Steam is applicable to the disinfection of bedding, clothing, fabrics of all kinds, and a great variety of other objects, provided certain precautions are taken to prevent shrinking, staining, running of colors, etc. Steam shrinks woollens and injures silk fabrics; it ruins leather, fur, skins of all kinds, rubber shoes, oilcloth, and articles made of impure rubber or containing glue, varnish, or wood.

Food of all kinds is sterilized by steam in the process of canning.

It is important in disinfecting with steam, whether with streaming steam or steam under pressure, to *expel the air from the apparatus*. The air, being a poor conductor of heat, forms dead spaces and prevents the steam coming in direct contact with the articles to be disinfected, thereby defeating the object to be attained. As steam is lighter than air the latter can best be expelled from the apparatus by admitting the steam from above, in which case the descending column of steam forces the air out at the bottom. If the steam is admitted at the bottom it swirls up, making a nearly uniform mixture with the air, and while the temperature quickly rises in the apparatus the air escapes mixed with the steam, so that it takes a long time and an unnecessary waste of steam to drive out the contained air.

Disinfection with streaming steam may be accomplished in many ways without the use of special apparatus. For rough and ready work on the railroad the objects to be disinfected may be hung in a freight-

car and the steam brought from the locomotive. On board a vessel one of the compartments above the water-line may be filled with steam from the boiler. Objects may be steamed in any rough structure wherever a boiler is found to furnish the steam. Such a structure need not be tight, for the streaming steam escaping from the cracks produces a circulation and favors penetration.

In the laboratory small objects are disinfected in streaming steam in the Arnold steam sterilizer or the Koch steamer.

On account of the great certainty with which steam under pressure acts it is the favorite method in practical disinfection, especially where sterilization is required, and devices for applying this process on a large scale have reached a high degree of perfection. The smaller forms of steam sterilizers under pressure are known as digestors or autoclaves and the larger ones as steam disinfecting chambers.

**The Autoclave.**—The autoclave, digester, or steam sterilizer consists of a closed kettle usually made of copper and sufficiently strong to withstand the pressure. Water is placed in the kettle and the heat is applied to the bottom, usually by means of several Bunsen gas jets. The apparatus is surrounded as high as the shoulder, where the lid is attached, with a metal jacket which serves the purpose of bringing the heat of the flame in contact with the entire surface of the kettle. The lid is made to fit tightly by means of screw bolts and a rubber gasket. A thermometer, pressure gauge, safety valve and a small opening with a stopcock for the purpose of allowing the escape of the air are provided. If all the air is not expelled from the apparatus the dead spaces will have a much lower temperature than that registered on the thermometer. For instance, the steam itself may register a temperature of  $130^{\circ}$  C., while test fluids exposed may only reach  $70^{\circ}$  to  $80^{\circ}$  C. Therefore, in using this form of sterilizer it is customary to allow the steam to escape in full force for several minutes before permitting the pressure to rise.

In the sterilization of liquids, for which this apparatus is frequently used, it is important, at the conclusion of the process, not to take off

FIG. 166.—SECTION THROUGH ARNOLD STEAM STERILIZER.

the lid or open the valves, or in any other way release the pressure until the apparatus has cooled; otherwise the condensed steam causes a diminished pressure, in which the heated liquids will boil energetically, resulting in a bubbling over, a blowing out of stoppers, or a bursting of the flasks. It is therefore necessary to wait until the pressure is zero, as registered on the gauge; or, better, until the condensing steam produces a partial vacuum and the air is automatically sucked in through the vacuum valve, which is sometimes fitted in the lid of the apparatus for this very purpose.

FIG. 167.—SECTION THROUGH AUTOCLAVE.

water when put in the autoclave. This is for the purpose of insuring that steam will be in contact with all surfaces.

**The Steam Chamber.**—The steam disinfecting chamber has reached a high degree of usefulness through the gradual perfection of the details of its working parts. These chambers are somewhat complicated and their mechanical construction must be mastered in order to insure reliable results. Steam disinfecting chambers may be used with streaming steam or with steam under pressure; with formaldehyd gas alone, or with this gas in combination with dry heat; and, finally, with various combinations of these methods with or without a vacuum.

The disinfecting chamber itself may be rectangular or cylindrical in shape, the former giving more effective space, the latter being a stronger and cheaper method of construction. The chamber is built of an inner and outer shell forming a steam jacket, as shown in Figs. 169

and 170. The federal regulations<sup>9</sup> require 121° C. (15 pounds) for 30 minutes for steam sterilization of glassware and rubber tubing. Glassware and rubber tubing must be moistened immediately before steam sterilization and each flask or hollow apparatus should contain one-eighth of its volume of

The federal regulations<sup>9</sup> require 121° C. (15 pounds) for 30 minutes for steam sterilization of glassware and rubber tubing. Glassware and rubber tubing must be moistened immediately before steam sterilization and each flask or hollow apparatus should contain one-eighth of its volume of

<sup>9</sup> Regulations U S. Public Health Service, October 1, 1919.

and 170. The steam jacket serves several purposes. By heating the contents of the disinfecting cylinder before the steam is turned in it avoids condensation. During the process of disinfection it helps keep the steam in the chamber "live," thereby preventing the wetting of the objects exposed. After the disinfection is finished and the chamber opened the heat from the steam in the jacket may be used to dry the objects which have just been steamed. Therefore, in using this apparatus

FIG. 169.—CROSS SECTION THROUGH STEAM DISINFECTING CHAMBER.

for disinfecting with steam, either with or without pressure, the steam is kept circulating in the jacket from the beginning to the end of the process.

In the jacket the steam has a perfectly free circulation, so that the entire disinfecting cylinder, with the exception of the doors, is surrounded by live steam. The outer shell of the jacket is insulated with a covering of sectional magnesia, asbestos, or some other non-conducting substance.

The steam from the boiler passes through the main steam pipe A (Fig. 171) to the pressure-reducing valve (2), and thence to the bottom of the jacket at B, B.

Into the disinfecting chamber itself the steam can be admitted

only from the jacket, through the circulating pipes, A, C, B (Fig. 169), and after circulating through the disinfecting chamber in the direction as shown by the arrows is allowed to pass out with the drip through the drain D (Fig. 170). Upon the completion of the process

FIG. 170.—LONGITUDINAL SECTION THROUGH STEAM DISINFECTING CHAMBER.

the steam may be blown off through the vacuum pipe F, but this outlet should not be used during the steaming because the desired circulation would not be obtained.

It will be noticed that the steam is admitted at the *bottom* of the

*jacket*, and at the *top* of the disinfecting chamber, as shown in Fig. 169. The object of admitting the steam at the top of the disinfecting chamber is to favor the expulsion of the air through its outlet at the bottom by means of the descending column of steam. Therefore, in order to expel

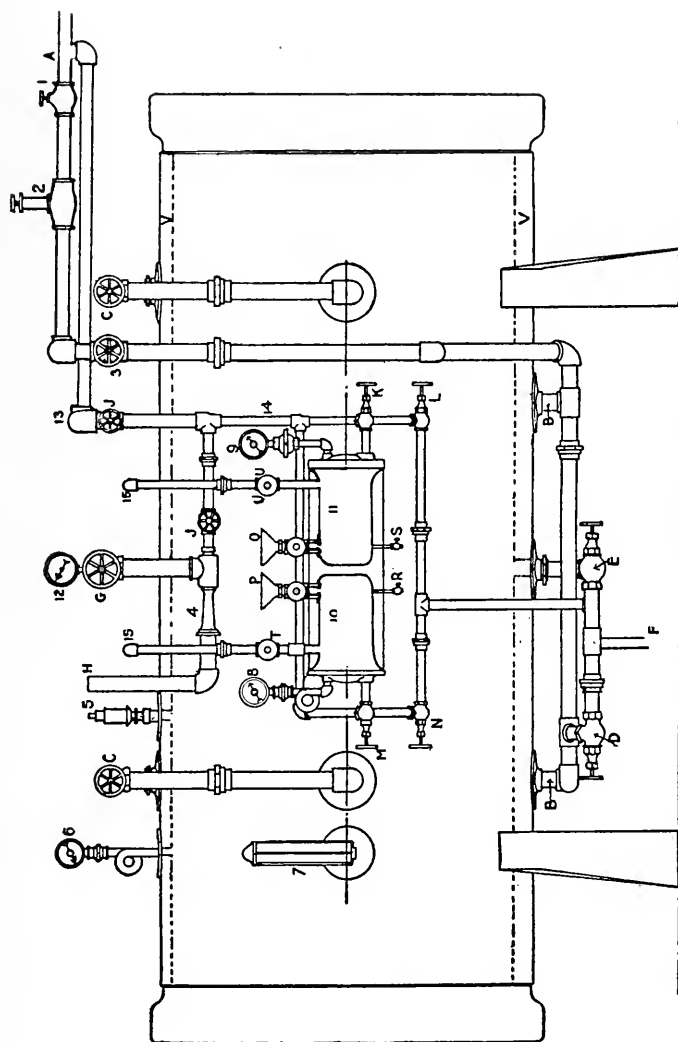

FIG. 171.—KINYOUN-FRANCIS STEAM DISINFECTING CHAMBER.

all the air and fill the chamber with steam it is essential to open the drain D (Fig. 170) while the steam is entering through B, B, and this outlet D should not be closed until steam escapes freely. In using the vacuum attachment to expel the air contained in the apparatus the *modus operandi* is somewhat different.

To determine whether all the air has been expelled, lead a pipe

from the exhaust to a bucket of water. Air reveals itself as bubbles; steam gives the well known hammer effect.

A partial vacuum may be obtained in steam chambers of this type with the ejector (4, Fig. 171). The object of the vacuum is to facilitate the penetration of the steam, which rushes into all the interstices of fabrics and inaccessible places, to take the place of the air which has been withdrawn. The ejector works upon the familiar principle of the water vacuum pump, the air being drawn or sucked along with the current. With a pressure of 80 pounds in the boiler and the valve J (Fig. 171) wide open, the ejector will produce a partial vacuum of 15 inches in one of the largest sized chambers in one minute, which is very much quicker than can be accomplished with the ordinary forms of piston pumps.

Any steam disinfecting chamber may have attached to it an apparatus for generating formaldehyd gas, so that objects that are injured by exposure to steam may be disinfected with formaldehyd, plus dry heat. Before the formaldehyd is admitted into the chamber a partial vacuum may be established by means of the ejector. In this way the penetration of the gas is very much facilitated.

In the best patterns the steam disinfecting cylinders are open at both ends, so that the infected objects may be introduced from one end and taken out from the other, which diminishes the risk of reinfesting them. The joint between the door and the chamber is made tight by means of a heavy rubber gasket. The door should not be pressed against this gasket more firmly than is found necessary to retain the steam, otherwise the rubber will soon be rendered useless. When not in use the door should be kept open; otherwise, on cooling, the metal will adhere to the rubber gasket. This may be prevented to a certain extent by keeping the rubber gasket covered with graphite.

In addition to the above-mentioned attachments the disinfecting chambers are also supplied with a thermometer (7, Fig. 171). The thermometer, however, may be so close to the jacket that it is influenced by the heat in the jacket, which is usually higher than the temperature of the interior of the chamber. The thermometer should be in the door, or arranged to give trustworthy results. In disinfecting with steam under pressure the temperature is a more reliable guide than the pressure. There are forms of mercurial and metallic thermometers that make an electric contact when a certain temperature is reached, and which may be connected to ring a bell. They have a decided advantage in that they may be placed anywhere within the chamber, even in the center of bundles, etc., and are more trustworthy than any form of mercurial instrument fastened through the heavy metallic walls of the apparatus.

An ingenious form of thermometer, made to register when the temperature reaches 100° C., has been designed by Merk, and is shown in the accompanying illustration (Fig. 172). A small stick of the me-

tallic substance which is supplied with the instrument and which melts at exactly  $100^{\circ}$  C., fastened at A, keeps the electrodes at B and C apart. The entire thermometer D is then placed in the box E for protection, and this is placed in the chamber or in the inside of bundles to be disinfected. The insulated wires from F and G are connected with a battery and bell. As soon as the temperature reaches  $100^{\circ}$  C. the little metal stick melts, the contact is made between B and C, and the bell rings. This form of thermometer is more accurate than the pyrometers, which depend upon the contact being made by the unequal expansion of a compound metal bar, for the reason that moisture collects upon the electrodes and an electric contact is sometimes made before the metal parts actually touch, thereby giving false readings.

The most accurate instrument for this purpose is the thermo-couple. Very satisfactory self-recording thermometers based upon the principle of expanding gases are made by the Taylor Instrument Company (page 790).

Steam chambers must always be provided with galvanized or copper hoods to prevent rust-stained drip from soiling the clothing and other objects exposed to the steam; gauges to indicate both vacuum and steam pressure, and a safety valve to prevent over-pressure in the chamber. The amount of pressure from the boiler is regulated by a reducing valve in the main steam pipe.

For convenience in handling the goods cars are provided, of light wrought-iron construction, with movable trays made of galvanized screens; also bronze hooks at the top of the car, permitting the articles to be laid upon the trays or to be hung up on the hooks.

In the accompanying diagram (Fig. 173) the method of installing the steam chambers in the disinfecting shed of a quarantine station is shown. It will be noted that the cylinders are open on both ends, and that a dividing wall running across the building separates the receiving end, where the infected objects arrive and are prepared for disinfection, from the discharging end, where the contents of the chamber are aired, dried, and repacked after disinfection.

This separation is essential where a large amount of disinfection is done for a variety of diseases, as, for example, in a municipal disinfecting establishment or at the quarantine station of a busy port. It is true that the virus of certain diseases is not apt to contaminate the surroundings, and in such cases there would be little risk in taking the disinfected articles out of the same end of the chamber from which they are put in, especially if the exposed surfaces are mopped with a disin-

FIG. 172.—AUTOMATIC THERMOMETER.

fectant in the interim. But this is a risk that need not be taken; in fact, all well-regulated disinfecting plants maintain a rigid separa-

FIG. 173.—PLAN SHOWING THE METHOD OF INSTALLING THE DOUBLE-ENDED STEAM CHAMBERS AT A NATIONAL QUARANTINE STATION.

tion between the two sides, never allowing both doors of the chamber to be open at the same time, and providing two sets of workmen, one for the "infected" and one for the "disinfected" side.

The chambers must be loaded with care in order to obtain reliable

results and to avoid injuring the articles exposed to the process. The packages must not be too large or crowded too closely, for, although the vacuum facilitates the penetration of the steam, there is a limit in this regard; it takes so much longer for disinfecting agents to penetrate dense packages and bundles that there is little saving of time and a distinct loss in trustworthiness. Steam cannot penetrate compressed bundles of rags, bales of cotton, feathers, hair, or other packages of merchandise which are often presented for disinfection, except by aid of the vacuum.

## CHAPTER III

### CHEMICAL AGENTS OF DISINFECTION

#### GASEOUS DISINFECTANTS—FUMIGATION

A germicidal gas would be an ideal weapon for destroying such invisible foes as we have to deal with in public health work, especially for terminal disinfection. By reaching all portions of a room or confined space a gas lessens the risk of overlooking any surface upon which the infective agent may be lodged, but an efficient gas for this purpose is still to be discovered.

There is practically only one gas suitable for general application, viz., formaldehyd. It is not poisonous, does not injure fabrics, colors, metals, or objects of art and value. Formaldehyd, however, has distinct limitations, which are dealt with more in detail under the description of the gas.

Sulphur dioxid is too destructive for fabrics, colors, and metals for general use. It is a better insecticide than germicide. It is very poisonous to all forms of animal life, which makes it valuable in fumigating against insect and animal-borne diseases. It is used for the fumigation of the holds of ships, cellars, sewers, stables, and other rough structures infested with vermin.

Hydrocyanic acid gas is too poisonous to use in the household, and is limited in practice to the destruction of infection and vermin on board ships, in warehouses, greenhouses, granaries, railroad cars, and other uninhabited or isolated structures.

The very poisonous and destructive nature of chlorin gas contracts its usefulness to narrow limits.

*None of the gaseous agents can be depended upon for more than a surface disinfection. They all lack the power of penetration.* Practically all the gaseous agents are not disinfectants but fumigants. See page 266.

**Preparation of the Room.**—The preparation of a room or space to be fumigated with a gas is a matter of some importance. A larger amount of gas than is thought possible is lost through leaks, by diffusion, by absorption and in other ways; therefore the room should be made tight, all cracks and crevices should be well closed by pasting paper over them or by caulking with suitable material of some kind. Do not forget to close the registers, flues, hearths, and ventilators, and look carefully for

openings in out-of-the-way places. Then expose the objects in the room so that the gas may have ready access to all the surfaces. Move bureaus, beds, and furniture away from the walls; open doors of closets, drawers of bureaus, lids of boxes, and the like so that the gas may freely enter and diffuse to all corners. *None of the gases can be depended upon to disinfect clothing, bedding and fabrics.*

While the articles in the room must be arranged so that the gas may freely gain access to all surfaces possible, the mistake must not be made of going to the opposite extreme of disarranging the contents of the room too much, for the same surfaces should be exposed to the gas that were exposed to the infection.

The strength of the gas and time of the exposure necessary to insure disinfection have been determined by exact laboratory experiments, but the conditions found in actual practice are so variable that we must allow for a liberal excess to make up for inevitable wastage. Wind pressure also seriously influences the efficiency of gaseous disinfectants in a confined space. Much more air than is commonly thought possible forces its way through cracks and through the walls themselves. The wind pressure may thus drive the fumigating gas entirely away from one side of the room. It is only necessary to stand upon the leeward side of a structure being disinfected with sulphur dioxid or formaldehyd to realize the great quantity of gas blown from the enclosure. See page 266.

**Formaldehyd Gas.**—Formaldehyd<sup>1</sup> is the most generally useful and one of the best disinfecting gases that we possess. Its superiority depends upon its high value as a germicide, its non-poisonous nature, and upon the fact that it is not destructive. The secret of successful disinfection with this substance is to obtain a large volume of the gas in a short time.

Formaldehyd (HCHO) exists in at least three well-recognized isomeric states:

(1) Formaldehyd (formic aldehyd) is a gas at ordinary temperatures, colorless, and possessing slight odor, but having an extremely irritating effect upon the mucous membranes. At a temperature of about  $-20^{\circ}$  C. the gas polymerizes into paraformaldehyd, known commercially as paraform.

(2) Paraform is a white substance, unctuous to the touch, soluble in both water and alcohol. It consists chemically of two molecules of formaldehyd. It is this substance which is supposed to compose the commercial solutions of formaldehyd known as formalin, formol, etc.

(3) Trioxymethylene is formed by the union of three molecules of formaldehyd. It is a white powder giving off a strong odor of the gas. It is but slightly soluble in alcohol and water.

Formaldehyd gas possesses about the same specific gravity as air;

<sup>1</sup> Formaldehyd is the gas, formalin is the aqueous solution of the gas.

it diffuses slowly, although somewhat better than sulphur dioxid. Formaldehyd combines with nitrogenous organic matter. A few drops added to the white of an egg will prevent its coagulation by heat. The formaldehyd unites with the albumin to form a totally new compound. Combined with gelatin it keeps that substance from liquefying. It is from this property of combining directly with the albumins forming the protoplasm of the microörganisms that formaldehyd is supposed to derive its power as a germicide. It is perfectly plain, therefore, why there must be direct contact between the gas and the germ in order to accomplish disinfection.

Formaldehyd also unites readily with the nitrogenous products of decomposition, forming new chemical compounds which are both odorless and sterile. It is thus a true deodorizer in that it does not mask one odor by another still more powerful, but forms new chemical bodies which possess no odor.

Formaldehyd apparently has no detrimental effects upon silks, wools, cotton and linen. It does not change colors, with the exception possibly of a slight effect upon some of the delicate aniline lavenders. An oil painting is not perceptibly altered after prolonged exposure to the gas. The metals are not attacked. It is this non-destructive property of the gas that renders it generally applicable. It is practically the only gaseous germicide which can be used in the richest apartments, containing objects of art and value, without fear of damage.

The commercial solutions known as formalin are said to contain 40 per cent. of formaldehyd gas. They are not always up to standard (average 36 per cent.), and, being volatile, there is a certain loss if not well kept. In winter there is a decided deterioration, owing to the polymerization and precipitation of trioxymethylene. This substance is often found in abundance at the bottom of the bottle or carboy as a white precipitate. For these reasons it is well to use an excess of the liquid in practical work if the exact strength of the formalin has not recently been determined.

Formalin solutions of commerce are almost all acid in reaction, due in part to formic acid. Some of the commercial solutions also contain a certain amount of wood alcohol (about 10 per cent.) which is added to increase their solubility and stability.

A certain amount of heat and moisture is necessary to obtain successful disinfection with formaldehyd gas. The exact amount of moisture necessary depends somewhat upon the temperature. As a general working rule it may be stated that *if the temperature is below 65° F. or if the relative humidity is below 60 per cent. the results become irregular; much below these figures the results are unreliable, especially if the space is both cold and dry.* Formaldehyd polymerizes at low temperatures, therefore in cold weather it may be necessary artificially to warm

the room to be disinfected. In dry weather moisture should be added to the room.

Formaldehyd gas cannot be depended upon to accomplish more than a surface disinfection. Under ordinary circumstances it possesses small powers of penetration. The gas polymerizes in the meshes of the fabric and is deposited as paraform upon surfaces. Large quantities of formaldehyd are lost by uniting chemically with the organic matter of fabrics, especially woollens, which further hinders its penetration. Therefore, formaldehyd gas cannot be relied upon to disinfect fabrics, especially quilted goods and materials requiring deep penetration.

Formaldehyd gas has the power of killing spores, although not with sufficient certainty to render it a trustworthy agent for infections such as anthrax and tetanus. It has the great advantage of killing dry microorganisms, although not quite so readily as when they are moist.

Bacteria exposed directly to the action of a concentrated volume of formaldehyd gas are killed almost instantly, but in practical work it is necessary to prolong the time of exposure to 6 or 12 hours, as it takes considerable time for the gas to permeate to all the corners and dead spaces of a room. Bacteria are not always directly exposed upon the surface of objects, as they are in laboratory experiments, and, furthermore, they are frequently imbedded in albuminous matter or in dust, both of which retard the action of the gas.

Formaldehyd gas is not very toxic to the higher forms of animal life, although it stands at the head of the list of germicides. Long exposure to weak atmospheres of the gas sufficient to kill germs has but slight effect upon animals. Guinea-pigs, rats, mice, and rabbits exposed to concentrated atmospheres are not killed after half an hour's exposure. The only effect produced is a violent irritation of the mucous membranes of the respiratory tract, from which the animals may subsequently die. Microorganisms exposed to this same concentration of the gas are killed almost instantly.

Formaldehyd is rapidly absorbed from all parts of the gastro-intestinal tract and lungs, and may be excreted again by them. It is rapidly oxidized in the body to formic acid and carbonates. There is also a small amount of a dialyzable compound formed in the blood which is most probably hexamethylenamin since the latter is found in the urine. Small amounts of formaldehyd may pass through the body without causing apparent inflammation, while large amounts always cause some.

Formaldehyd is not an insecticide. In the strongest concentrations of the gas obtainable it seems to have practically no effect upon roaches, bedbugs, and insects having strong chitinous coverings. It may kill the frailer insects, but its action is uncertain; thus mosquitoes may live in a weak atmosphere of the gas over night.

Upon the completion of the time required to disinfect a room it is

best to open all the doors and windows and let the gas blow away. This may be a troublesome procedure. If the windows can be reached from the outside it is easy enough, but if the room must be entered it is advisable for the operator to cover his mouth and nose with a moist towel and act quickly. It was formerly the custom to neutralize the gas with ammonia, but this is little practiced now. The ammonia neutralizes the formaldehyd by the production of hexamethylenetetramin.

Formaldehyd may be released from its watery solution by any actively oxidizing agent. Potassium permanganate is the best, for it liberates the largest volume of gas, and in the shortest time; but, on account of the high cost of this chemical during the war, the following may be

substituted: bleaching powder, unslacked lime, sodium dichromate, barium oxid. Permanganate liberates about 60 per cent. of the gas; dichromate, about 30 per cent., and bleaching powder about 25 per cent. In the case of bleaching powder only about 3 per cent. of the total gas set free is chlorin.

*The Permanganate - Formalin Method.*—Use 500 c. c. of formalin and 250 grams of potassium permanganate for each thousand cubic feet of air space. The permanganate is first placed in a bucket or basin and the formalin poured upon it. An active effervescence takes place and considerable heat is evolved; therefore a pail of sufficient capacity, and especially of sufficient height, should be

FIG. 174.—FLARING TOP TIN BUCKET FOR GENERATING FORMALDEHYD BY THE PERMANGANATE METHOD. Height 15 inches, diameter 10 inches at base, 15 inches at top of flare.

used to prevent splashing or boiling over. In Board of Health work it is advisable to have galvanized iron pails made for this purpose with a flaring top. The floor should be protected against the heat by placing the bucket upon a brick, board, or other suitable device.

When the permanganate of potassium and formalin are brought in contact very active oxidation takes place, with the production of formic acid and heat. It is the heat that liberates the formaldehyd gas. Chemically, therefore, the method is a wasteful one, but practically a very serviceable one. It was first described by Johnson of Sioux City, Iowa, in 1904. In the same year Evans and Russell of Augusta, Maine, used the method.<sup>2</sup>

<sup>2</sup> 14th Ann. Rep., State Board of Health of Maine, 1906.

The formula recommended by the Pennsylvania Department of Health is:

Sodium dichromate .....	10	ounces
Formalin .....	16	"
Commercial sulphuric acid .....	1½	"

The sulphuric acid can be added to the formalin and the mixture kept on hand for use; polymerization in cold weather can be avoided by the addition of glycerin, 1½ ounces. The acid formalin is poured on the crystals of sodium dichromate and formaldehyd gas is at once liberated.

*The Formalin-Lime and Aluminium-Sulphate Method.* — This method was first described by Walker of the Department of Health, Brooklyn, N. Y. It is somewhat slower than the potassium permanganate method, but otherwise appears to be just as efficient.

The proportions for each 1,000 cubic feet are as follows:

<i>Sol. A.</i> —Aluminium sulphate .....	150	grams
Dissolved in hot water .....	300	c. c.
<i>Sol. B.</i> —Formalin (40 per cent. CHO <sub>2</sub> H) .....	600	c. c.
<i>Lime.</i> —Unslaked lime .....	2,000	grams
Mix solutions A and B and pour upon the lime.		

In practical work 20 to 25 pounds of the commercial aluminium sulphate is dissolved in 5 gallons of hot water. This is sufficient to mix with 15 gallons of a 40 per cent. formaldehyd solution and then used in the proportions as stated above. The lime should be freshly burned, broken into small particles, and should slake rapidly in cold water. The lime is placed in a large bucket. The formalin and aluminium sulphate solutions should be mixed and poured over the lime. In a few minutes the lime begins to slake and the heat evolved drives off the formaldehyd gas.

*The barium-formalin method* was developed by Candall,<sup>3</sup> and consists of one pint of formalin (solution of formaldehyd U. S. P.) and one and one-half pounds barium oxid containing not less than 78 per cent. barium dioxid for each 1,000 cubic feet to be disinfected.

*Bleaching-Powder Method.*—Place in a mixing pan 12 ounces of chlorinated lime, 4 ounces of water; stir to a paste. Then pour 1 pound formalin over the moistened lime. This is sufficient for 1,000 cubic feet.

*The Spraying Method.*—Spraying formalin is a satisfactory and simple method of disinfecting small inclosures, such as wardrobes, closets, and cabinets. It is not practical for larger rooms. If the formalin is sprayed directly upon the objects to be disinfected they enjoy

<sup>3</sup>U. S. Naval Medical Bull., Oct., 1917, p. 519.

the direct germicidal action of the substance in solution and, further, are bathed in the gas which is slowly evolved. The method is particularly serviceable for the disinfection of bureau drawers, closets, valuable books and manuscripts, jewelry, objects of art, etc. When used to disinfect small rooms suspend a bed sheet from a line stretched across the middle of the room. An ordinary bed sheet presenting a surface of about 2 by 2½ yards is required for every 1,000 cubic feet of space of the room. Properly sprinkled this will carry, without dipping, 8 ounces of formalin. The ordinary sprinkling pot used by florists can be used to spray the sheets and a liberal excess should be used. The room should remain closed not less than eight hours.

The other methods for disinfecting with formaldehyd gas are not described because most of them are unreliable, and none of them is as serviceable in practical work as the formalin-permanganate method or the formalin-lime method.

**Sulphur Dioxid.**—Sulphur dioxid ( $\text{SO}_2$ ) is not an efficient germicide, but is exceedingly poisonous to mammalian and insect life. It is this property which makes it of especial value as a fumigant against diseases spread by rats, mice, flies, fleas, mosquitoes, etc.

The action of sulphur dioxid as a germicide depends upon the presence of moisture. The dry gas is practically inert against bacteria. Sulphur dioxid cannot be depended upon where penetration is required. Its action is merely upon the surface. It does not kill spores.

Sulphur dioxid possesses the advantage of being cheap and readily procurable. There is hardly a crossroad store in the country where a reasonable quantity of sulphur, either in the form of flowers or in rolls or sticks under the name of brimstone, cannot be obtained. Sulphur dioxid is especially applicable to the holds of ships, freight-cars, granaries, stables, out-houses, and similar rough structures—particularly if infested with vermin.

The disadvantages of sulphur dioxid as a disinfecting agent are such as to contract its application to rather narrow limits. It bleaches all coloring matter of vegetable origin and many anilin dyes. It attacks almost all metals; it acts upon cotton and linen fabrics so as seriously to weaken their tensile strength, especially if starched.

Sulphur dioxid is a heavy, colorless, irrespirable gas with a peculiar suffocating odor and irritating properties. It has a density of 2.4. On account of the heavy specific gravity as compared with air it diffuses slowly and then settles toward the bottom of the compartment.

Cold water takes up more than 30 times its volume of sulphur dioxid. The solution contains sulphurous acid ( $\text{H}_2\text{SO}_3$ ), and it is in reality this acid that is the disinfecting agent. The dry gas is therefore inert and moisture is essential in order to obtain any germicidal effect. It is also this acid and some sulphuric acid which has such a destructive effect

upon fibers, colors, and metals. The corrosive action of these acids upon fabrics takes place slowly, and the damage may largely be obviated if they are washed at once. Metal work may be protected by coating it with a thin layer of vaselin or heavy-bodied oil.

Sulphur dioxid may readily be condensed into a clear liquid by either cold or pressure or a combination of both. At ordinary atmospheric pressure it condenses if the temperature is reduced to  $-18^{\circ}$  C., which is about the temperature of a mixture of ice and salt. At ordinary temperatures it liquefies if the pressure is raised to about four atmospheres, that is, 60 pounds. This liquid is a stable substance when kept well sealed and protected from the action of the air. It rapidly volatilizes when poured into an open vessel. It is now found in commerce and is one of the methods used for producing the gas for fumigating purposes.

The complete combustion of 1 pound of sulphur in a space of 1,000 cubic feet will theoretically produce 1.115 per cent. of sulphur dioxid, but this amount cannot be obtained in practice because the sulphur of commerce contains impurities such as sulphate of lime and sand, and a portion of the burning sulphur is always oxidized to the formation of ill-defined compounds. Therefore one pound may be considered as producing approximately 1 per cent. of the gas by being burned in 1,000 cubic feet of space, and five pounds will generate approximately 5 per cent., which is the maximum theoretical amount obtainable by burning sulphur in a confined space. Five pounds per 1,000 cubic feet is the amount generally used when a germicidal action is desired. Somewhat less, two to four pounds, is sufficient to destroy insects and rats. See pages 517 and 269.

The amount of moisture necessary to convert sulphur dioxid into sulphurous acid is readily computed. It will be found that one-fifth of one pound of water should be volatilized for each pound of sulphur burned. The water may be added in the form of steam or in the form of a finely divided spray, or it may be vaporized by the heat generated by the combustion of the sulphur itself. The latter method is the one that commends itself in practical use, and is described under the "pot method."

While moisture is essential for the germicidal action of sulphur dioxid, it is not necessary in order to kill insects and small mammals. Dry sulphur dioxid is quite as efficacious against rats, mice, fleas, flies, mosquitoes, bedbugs, roaches, etc., as the moist gas.

In disinfecting with sulphur dioxid it is necessary to seal the compartment tightly. The gas is disengaged so slowly that it may escape through cracks and crevices almost as fast as it is formed. In cold weather the heating of the room to be disinfected will greatly aid in the disinfecting action of the gas.

There are three well-recognized methods of fumigating with sulphur

dioxid, viz., (1) the pot method, (2) liquid sulphur dioxid, (3) sulphur furnace.

*The Pot Method.*—The pot method is at once the easiest, cheapest, and probably most efficient method of using sulphur dioxid. The only materials required are iron pots and some sulphur. The best way to apply the method is by placing the sulphur in large, flat, iron pots known as Dutch ovens. Not more than 30 pounds of sulphur should be placed in each pot. The sulphur is preferably used in the form of flowers of sulphur. If it is in sticks or rolls it should be crushed into a powder, which may conveniently be done by placing the sulphur in a stout box and pounding the lumps with a heavy timber. The pot holding the sulphur should be placed in a tub of water, as shown in Fig. 175. The water not only diminishes the danger from fire and protects the floor, but by its evaporation furnishes the moisture necessary to hydrate the sulphur dioxid, upon which the disinfecting power of the gas depends. Thus the moisture is furnished automatically and does away with the necessity

FIG. 175.—THE POT METHOD OF BURNING SULPHUR.

for its introduction by means of steam or a spray. Although the specific gravity of sulphur dioxid is greater than that of air, when hot it rises, aided by the upward current produced by the burning sulphur. Hence the pots should not be on the floor, or at the bottom of the hold in the case of vessels, lest the cold gas settle and the flame, being deprived of oxygen, be extinguished before all the sulphur is burned. The pots may therefore be placed upon a table or box or, in the holds of ships, upon piles of ballast or on the "tween decks."

Roberts and McDermott<sup>4</sup> suggest that the sulphur be burned upon pans arranged upon a rack, as shown in Fig. 176, instead of pots. The advantages of this stack burner are that a large amount of sulphur may be more quickly burned in less time than is possible with the pot method. Further, the intense heat below each pan in the stack burner aids the complete and rapid burning of sulphur in the pans above it. A stack burner will burn sulphur of too poor a quality to give any satisfaction in the pots. The ground sulphur is placed in the pans, the surface of the sulphur is moistened with alcohol, and ignited. Each shelf should be lighted separately to save time. The upper pan or pans may be filled with water to hydrate the sulphur dioxid necessary for its germicidal action.

The sulphur may be lighted by means of hot coals or a wood fire,

<sup>4</sup> *Public Health Reports*, U. S. P. H. and M. H. S., March 31, 1911, Vol. XXVI, 13, p. 403.

but the most reliable way to get it well lighted is by alcohol, turpentine, or kerosene on a pledget of waste. Make a little crater of the sulphur, soak liberally with alcohol, and ignite. The sulphur then burns in the center, and as it melts runs down from the sides and forms a little lake at the bottom of the crater. If the sulphur is heaped up in a mound in the pot the flame is liable to go out.

Upon the principle of not putting all our eggs in one basket, it is best to have a number of pots when a large compartment is to be fumigated. A pot should contain not more than 30 pounds of sulphur, and the pots should be well distributed in various portions of the place to be disinfected.

Use 5 pounds per 1,000 cubic feet where a germicidal action is

FIG. 176.—LARGE STACK BURNER FOR SULPHUR, WITH 15 OF THE 18 PANS REMOVED TO SHOW CONSTRUCTION.

desired, and at least 2 pounds per 1,000 cubic feet for insecticidal purposes. For the destruction of bacteria an exposure of from 6 to 24 hours is necessary, while for the destruction of vermin from 2 to 12 hours is sufficient, depending upon the size and shape of the compartment to be treated.

*Liquid Sulphur Dioxid.*—Liquid sulphur dioxide, commonly known as sulphurous acid gas, while efficient, is about ten times as expensive as burning sulphur by the pot method. It has the advantage of liberating a large volume of the gas rapidly, thereby facilitating its dispersion. Further, the use of liquefied sulphur dioxide has the advantage of avoiding the danger of accidental fire.

One pound of burning sulphur will produce about 2 pounds of sulphur dioxide:  $S(32) + O_2(32) = SO_2(64)$ . Therefore 2 pounds of the liquid sulphur dioxide is necessary to produce the same volume of sulphur dioxide as is generated from one pound of the burning sulphur.

The method of using the liquid sulphur dioxid is very simple. If the substance is bought in small tins it is only necessary to cut the lead pipes in the tops of the necessary number of cans and invert the latter in an ordinary washbowl or iron pot, when volatilization rapidly occurs. All the cans must be cut simultaneously and the operator must act quickly and be prepared immediately to leave the room and shut the door. If the substance is contained in glass or metallic siphons the necessary amount of liquid sulphur dioxid can be projected from the outside through a pipe passed through the keyhole or other aperture. A suitable receptacle should be arranged on the inside to catch the drip and frozen mass which forms as a result of the expansion. In order to obtain the maximum disinfecting power with this method it is necessary to introduce moisture. This may be done by placing open pans of boiling water in the room, by injecting steam, or by a fine spray of water.

*The Sulphur Furnace.*—The sulphur may be burned in an apparatus of special construction known as a sulphur furnace, from which

FIG. 177.—LIQUEFIED SULPHUR DIOXID IN TIN CAN.

the resulting fumes are blown through a system of pipes into the room or hold of a vessel to be disinfected. Two forms of sulphur furnace are used: (1) the Kinyoun-Francis furnace, and (2) the Clayton furnace.

This method requires expensive and cumbersome machinery and has little to recommend it over the simpler pot method except that a large percentage of the gas may be blown into a given space. The pot method at best cannot produce an atmosphere containing more than 4 per cent. of sulphur dioxid, whereas it is theoretically possible to charge a confined space with a higher percentage of the gas by means of the furnace. In practice this is not possible without burning a great excess of sulphur and by expending a very long time, for the reason that the fumes first entering mix with the air and as the gas continues to flow into the space it displaces about an equal quantity of this mixture of sulphur dioxid and air, so that, as a matter of fact, in actual practice only about  $2\frac{1}{2}$  to 6 per cent. of the gas is usually obtained in the holds of vessels by the sulphur furnace.

It is advisable in using the sulphur furnace to arrange the pipe admitting the gas into the room as near the floor as possible. In disinfecting the holds of vessels the pipe is usually let down the hatchway until

it is near the bilge. The heavy gas collects at the bottom and gradually ascends, displacing the air, so that it is important to allow an opening of some sort for the exit of the air near the top of the compartment that is being disinfected. This opening should not be closed until the gas escapes freely.

The *Kinyoun-Francis furnace* consists of an iron pan upon which the sulphur is burned. Under this pan is a firebox with ashpit and necessary drafts. The firebox is designed to hold a light fire of wood or shavings and is intended to heat the sulphur pan sufficiently to ignite the sulphur when thrown upon it at the beginning of the operation. This part of the apparatus is unnecessary, as the sulphur may be ignited more simply by means of some alcohol, turpentine, or kerosene on waste, or a few live coals. When once lighted there is no trouble in keeping the sulphur burning.

The air enters at A, Fig. 178, through a valve arranged to regulate the amount of flow. It then passes over the burning sulphur in the direction shown by the course of the arrows to the fan. Fumes are compelled to take a devious course around the baffle plates and angle irons, as shown in the drawing, in order to insure complete combustion and to arrest sparks. From B the fumes are sucked to the fan, which is actuated by a steam engine or electric motor, and which forces the gas through the pipes to the place to be disinfected.

Running the fan at too high a speed may cause overheating of the pipes or the carrying over of sparks of burning sulphur. The proper amount of air should be carefully regulated so as to obtain complete combustion and the maximum amount of sulphur dioxide gas.

The pipe conducting the fumes from the sulphur furnace to the compartment to be disinfected gives a certain amount of trouble. It is apt to become clogged with sulphur which sublimates in the cooler parts. Ordinarily this pipe must be from 6 to 8 inches in diameter and may be made of smooth galvanized iron and the joints made tight with several layers of canvas saturated and coated with some fireproof paint. Rubber hose of this size is very expensive and soon vulcanizes.

No arrangement is made in this form of apparatus for adding water vapor to the sulphur fumes, which is necessary to obtain germicidal action. As a rule the holds of wooden vessels, in which sulphur fumigation is so much used, are usually so damp that the addition of more moisture is not necessary.

The *Clayton furnace* is a more compact apparatus than that just described. The sulphur dioxide is passed through a series of tubes surrounded by water, an arrangement corresponding in all respects to the tubular condenser of a low-pressure steam engine. The Clayton furnace is furnished with a Root blower, and has the advantage that a comparatively large volume of sulphur dioxide may be pumped rapidly through

pipes of small caliber without fear of overheating or fire. These furnaces are being installed upon ships for the purpose of fumigation at port and during the voyage for the destruction of rats, mice, and vermin. It is also an efficient fire extinguisher.

FIG. 178.—SECTION THROUGH DOUBLE SULPHUR FURNACE.

A portable sulphur furnace is a useful apparatus in municipal work, particularly in the fumigation of sewers, warehouses, stables, barns, and similar large, rough structures infested with vermin. This form of furnace was used in the fight against rats in the sewers of San Francisco in the anti-plague campaign. For the practical uses of sulphur in maritime quarantine, see page 514.

**Hydrocyanic Acid Gas.**—Hydrocyanic acid gas has practically no germicidal action, but is a very powerful insecticide. It is exceedingly poisonous to mammals, and will kill rats and mice with certainty. On account of its poisonous nature, it must be used with great care. It is so much easier to use than sulphur dioxide that it is finding favor in maritime quarantine work. Hydrocyanic acid gas is useful in the treatment of stables, granaries, outhouses, compartments of ships, sleeping-cars, day coaches, and similar isolated or uninhabited places for the destruction of vermin.

Creel<sup>5</sup> found that powdered potassium cyanid facilitates the evolution of the gas, which is lighter than air and rises; it, therefore, permeates a space more quickly than  $\text{SO}_2$ . Creel also found that hydrocyanic acid gas does not destroy bacteria. Creel and Faget<sup>6</sup> found that four ounces of potassium cyanid per 1,000 cubic feet is sufficient

<sup>5</sup> Creel, R. H., Public Health Reports, Vol. XXX, No. 49, Dec. 3, 1915, p. 3537.

<sup>6</sup> Creel, R. H., and Faget, F. M., Public Health Reports, Vol. XXXI, No. 23, June 9, 1916, p. 1463.

to kill mosquitoes in 15 minutes; five ounces per 1,000 cubic feet kills bedbugs and roaches in 1 hour, lice in 2 hours; two and one-half ounces per 1,000 c. c. kills fleas in 15 minutes. See pages 273 and 515.

**Chlorin.**—Chlorin is a germicide of considerable but uncertain power. It has little practical usefulness owing to its poisonous and destructive action. Both in its free state and its watery solution it has active deodorizing properties. Moisture is necessary for the disinfecting action of chlorin gas. At best chlorin, like all gases, is but a surface disinfectant.

Chlorin is an extremely irritating gas, and great care must be observed in its employment, for the inhalation of very weak proportions of the gas produces serious irritation, resulting in spasm of the larynx, bronchitis, and even in death. Chlorin is heavier than air (sp. gr. 2.47) and tends to fall. Therefore the vessel generating the gas should be placed in an elevated position in order to obtain anything like effective diffusion. Carpets, curtains, and fabrics generally are injured by its action, and the element is a very active bleaching agent.

The germicidal action of chlorin depends upon its great affinity for hydrogen. So strong is this affinity that it combines with the hydrogen of water in the presence of light, liberating the oxygen in its nascent state, thereby enabling the oxygen to exert its power upon organic matter. The value of chlorin as a deodorant depends upon its power of decomposing the offensive gases of decomposition such as sulphurated hydrogen and volatile ammoniacal compounds.

The most convenient method of generating chlorin gas is by decomposing  $11\frac{1}{2}$  pounds of calcium hypochlorite with 6 ounces of strong sulphuric acid. This produces sufficient gas for the disinfection of 1,000 cubic feet of air space, or the gas may be generated from:

Common salt .....	8 ounces	(240 grams)
Manganese dioxid .....	2 "	( 60 " )
Sulphuric acid .....	2 "	( 60 " )
Water .....	2 "	( 60 " )

The following reaction takes place:

Mix the water and the acid together and then pour the mixture over the salt and manganese dioxid in a glazed earthenware basin. The basin should rest on sand or in water.

Fisher and Proskauer have shown that in ordinary dry air 5.38 parts of free chlorin per 1,000 cubic feet of air space appear to be necessary to kill microorganisms. If the air is moist only 0.3 per cent. by volume in each 1,000 cubic feet of air is sufficient, disinfection being completed in 5 to 8 hours.

Free chlorin is much less useful than sulphur dioxid, since it is more difficult to control, more dangerous to manipulate, and more destructive in its effects.

Chlorin gas liberated from a compressed liquid state is used for the disinfection of water. See page 1139.

**Oxygen.**—The disinfecting power of oxygen depends largely upon the physical state in which it exists. For instance, oxygen in the air has comparatively feeble germicidal properties when compared with nascent oxygen or ozone. The germicidal action of oxygen depends upon its very active property of combining chemically with the albuminous matter of the cell protoplasm. The oxidizing properties of this element partly explain the purifying action of fresh air. The germicidal property of oxygen is greatly aided by the actinic rays in sunlight. While most bacteria require the free oxygen of the air for their growth and multiplication, there is a large class of organisms (the anaërobes) to which the oxygen of the air acts like a poison or strong antiseptic.

**Ozone.**—Ozone is an allotropic form of oxygen containing three atoms of that element instead of two. In sufficient concentration it is a powerful germicide and has lately been found of practical use in the sterilization of water on a large scale for the use of cities and towns. It has also been used for the sterilization of bandages and other objects. There is not sufficient ozone in the air normally to exert any appreciable oxidizing or disinfecting properties. It requires at least 13 parts per million in the atmosphere to exert a definite effect upon bacteria; even then the action is not penetrating. Such quantities are harmful to man. See pages 869 and 1129.

Ozone may be used to destroy odors of organic origin due to substances that may be oxidized, such as the odors in dissecting rooms, animal pens, and like places.

The New York State Commission on Ventilation found that ozone failed to remove body odors from the recirculated air of a school-room.

For the use of pyrethrum and other fumigants, see Insecticides, page 266.

## LIQUID DISINFECTANTS

These consist of substances either in solution or suspension. An enormous number of such disinfectants have been exploited, but to be of practical value they must not only be strongly germicidal, but must also meet the many exacting requirements of general practice. Such substances are few in number.

Almost any chemical substance under one condition or another has the power to retard the development or destroy the activity of microbial

life. We need only mention the well-known power of common salt or of sugar, both of which in sufficient concentration prevent the processes of fermentation and putrefaction. In weaker dilutions these same substances, on the contrary, favor growth of almost all the known bacteria.

The undeserved reputation of many chemical substances depends more upon their vile odor or judicious advertising than upon actual efficiency. Only those substances that have proved their worth by scientific tests and shown themselves to be trustworthy in actual practice will be discussed. See page 1374.

**Methods of Using Chemical Solutions.**—There are various ways of applying chemical solutions for disinfecting purposes. No method is trustworthy that does not thoroughly wet the object with the solution, so that there may be direct contact between the germ and the germicide.

As a rule this may best be accomplished by immersing the infected object in the solution. When this is not practicable the solution must be applied to the object. A favorite way of applying disinfecting solutions to surfaces, such as walls, ceilings, the holds of ships and other rough structures, is by means of a hose. The pressure is supplied either by elevating the tank containing the solution or by means of a pressure pump. As bichlorid of mercury is practically the only disinfectant used in this way, the pump should be made of iron and have no copper, brass, or steel parts exposed to the corroding action of the bichlorid of mercury.

In applying the disinfecting solution to the surfaces of a room or the hold of a ship the operator should begin at one corner of the ceiling, wetting that first, and then go over every portion of the walls systematically, from above downward. The floor comes last.

Solutions thus applied remain but a short time in contact with the surfaces to be disinfected. It is therefore an advantage to have the solution hot and strong and to have sufficient pressure, in order to obtain the mechanical cleansing effect produced by a vigorous stream.

Another method of applying disinfecting solutions to surfaces is by means of mops, brooms, and the like.

The pulverizer is very popular in France for the disinfection of walls and other surfaces with liquid disinfectants. The apparatus for this purpose consists of a metal cylinder fitted with a simple force pump which compresses the air in the reservoir. The solution does not come in contact with the pump. The current of air driven through one tube sucks the solution through the other and sprays it from the nozzle in a nebulous cloud, similar in principle to the well-known hand atomizers. It is easy to demonstrate, by using a colored solution upon a white wall or sheet, that a liquid sprayed in this way does not wet the entire surface. The method is therefore an unscientific and unreliable one when used with a non-volatile chemical.

Germicidal solutions are much more potent when used hot.

**Metallic Salts.**—The metallic salts which are used are mainly those of silver, mercury, bismuth, zinc and copper. The germicidal activity of many of these metallic salts when acting upon bacteria suspended in pure water is extraordinarily high, but this powerful action is enormously reduced in the presence of organic matter.

There is good evidence pointing to the belief that the metallic ions in aqueous solutions, owing to electrolytic dissociation, are the chief disinfecting agents.<sup>7</sup>

**Bichlorid of Mercury.**<sup>8</sup>— $\text{HgCl}_2$ , bichlorid of mercury or mercuric chlorid, commonly called corrosive sublimate, is one of our most valuable and potent germicides. It destroys all forms of microbial life in relatively weak solutions. It kills both germs and their spores. It is not a deodorant.

The disadvantages of bichlorid of mercury are that it corrodes metals, forms insoluble and inert compounds with albuminous matter, and is very poisonous. These disadvantages place distinct limitations upon its use.

Bichlorid of mercury will dissolve in 16 parts of cold water and 3 parts of boiling water. As it is not readily soluble in water, it is convenient to keep a saturated alcoholic solution on hand and use this to make the watery solution. A 25 per cent. solution may readily be made in alcohol, and by the addition of hydrochloric acid or ammonium chlorid this solution keeps well without precipitation.

The solution of bichlorid of mercury is rendered more stable by the presence of hydrochloric acid or a chlorid such as ammonium chlorid or common salt. Twice the weight of these substances should be added to the quantity of bichlorid used. If the solution is to be pumped or otherwise come in contact with metals it is better to use the salt than the acid, because the acid solution of bichlorid is very destructive to the metal parts of the pump and to the couplings and nozzle of the hose, particularly if made of copper or brass. Sea-water contains about 4 per cent. of salt, and is well suited for making bichlorid solutions. It is extensively used at seaport quarantine stations for this purpose.

The germicidal action of bichlorid solution seems to depend upon the reaction which takes place between the mercury and the protein of the germ. Geppert has shown that in the reaction which takes place between the bichlorid of mercury and the spores of anthrax the vitality of the latter may seem to be lost, but that the bichlorid may be precipitated from its combination by the action of ammonium sulphid, thus restoring the viability of the spore. The sulphur acts as an antidote.

Bichlorid of mercury is decomposed by lead, tin, copper, and other

<sup>7</sup>*Arch. f. Exp. Path. and Pharm.*, 32, p. 456, 1893.

<sup>8</sup>The use of bichlorid of mercury as a disinfectant dates from Koch's experiments in 1881. *Kaisl. Gesundg.*, Vol. I.

metals, and therefore should not be made or kept in metal receptacles. Lead pipes are rendered brittle and worthless. Care must therefore be exercised in using this solution about water-closets and house plumbing.

Corrosive sublimate is precipitated in alkaline fluids containing albuminous substances. The precipitate consists of insoluble and inert compounds; therefore corrosive sublimate should not be used for the disinfection of media containing much organic matter, particularly when the reaction is alkaline. It is not well suited to the disinfection of sputum and feces, for it forms an albuminate which retards penetration. It also unites chemically with sulphids and the caustic alkalies, so that it should not be employed as a disinfectant when these substances are present in any considerable amount.

To diminish the danger from accidents in households and hospitals bichlorid solutions should be colored with permanganate of potash or indigo or one of the aniline dyes.

Bichlorid of mercury is usually used in the proportion of 1 to 500 or 1 to 1,000. A solution of 1 to 1,000 is ample for the destruction of all the non-spore-bearing bacteria, provided the exposure is continued not less than half an hour and direct contact is assured.<sup>9</sup> To assure this contact a longer time should be allowed in practice. Many bacterial cells are killed almost at once when brought into direct contact with a solution of this strength, and the great majority perish within 15 minutes. The extra time allows for penetration and provides a factor of safety. Warm solutions are much more potent than cold. For spores a solution of 1 to 500 is necessary and an exposure of not less than one hour.

For practical work the solution may be made as follows:

Corrosive sublimate.....	1 dram		1 gram
Water .....	1 gallon		1 liter
Mix and dissolve.			

This is approximately a 1 to 1,000 solution. One ounce of this solution contains very nearly half a grain of corrosive sublimate.

**Silver Salts.**—The germicidal action of most silver salts closely resembles that of the corresponding mercuric compounds. Silver chlorid is insoluble and hence ineffective, but silver nitrate appears to resemble mercuric chlorid fairly closely. Silver cyanids, colloidal silver, and various organic compounds which yield free silver ions on solution in water, all appear to have inferior germicidal properties, although some of them find useful application in medical practice.

<sup>9</sup> The action of mercuric chlorid upon spores has been most carefully studied by Kronig and Paul (*Zeitschr. f. Hyg.*, 25, p. 1, 1897); by Madson and Nyman (*Zeitschr. f. Hyg.*, 57, p. 388, 1907); and by Miss Chick (*Journ. of Hyg.*, 8, p. 92, 1908).

For the prevention of ophthalmia neonatorum, silver nitrate (1 per cent.) is used in Crede's method; also argyrol (25 per cent.), which is a colloidal silver; or protargol (3 per cent.), which is a silver protein.

**Zinc Salts.**—Zinc salts have long been known to have antiseptic properties, and the chlorid especially has been used by Lister and others. Its germicidal action is far inferior to that of most mercury and silver salts. Chlorid of zinc ( $\text{ZnCl}_2$ ) was at one time highly valued as a disinfectant and is still extensively used despite the fact that it stands rather low in the list of germicidal agents. It has even weaker power as a disinfectant than ferrous sulphate. Five per cent. solutions are effective against anthrax spores, but a 2 per cent. solution is effective against most vegetative forms in a reasonably short time when acting in an aqueous medium. This activity is, however, much influenced by the medium in which it acts, since it is very rapidly precipitated by proteins, phosphates, etc., and therefore cannot be recommended as trustworthy. It has some power as a deodorant.

**Ferrous Sulphate.**—Ferrous sulphate has long been valued as a disinfectant on account of its property as a deodorant, and has been used extensively, being a comparatively cheap substance. Its germicidal power has been shown by laboratory tests to be rather feeble, so that it cannot be depended upon as a trustworthy disinfectant.

Ferrous sulphate ( $\text{FeSO}_4$ ), commonly called green vitriol, iron vitriol, or copperas, consists of large bluish-green crystals which slowly effervesce and oxidize in the air. It is soluble in about twice its weight of cold water, forming a greenish solution. It is a much less powerful germicide than the sulphate of copper, and is limited in use to the destruction of odors, and even for this purpose is not always successful. It is still used with lime for the clarification of turbid waters.

**Sulphate of Copper.**—Sulphate of copper ( $\text{CuSO}_4$ ) is about half as strong as bichlorid of mercury. It has a peculiar selective action in that it has a remarkable affinity for many species of algae which are killed in the proportion of 1 to 1,000,000. Algae are the most common cause of unpleasant odors and tastes in drinking water, and sulphate of copper may therefore be used to check or destroy their growth. See page 1143. In these great dilutions sulphate of copper will not kill the typhoid bacillus, so that it is not practical to use it as a disinfectant in water.

## COAL-TAR AND ITS PRODUCTS

**Coal-tar Creosote.**—Creosote is a highly complex refractile liquid obtained from the destructive distillation of wood or coal. Wood-tar creosote for medicinal use is obtained from beechwood; it is a complex mixture of phenoloid bodies, the proportions of which differ according to

the modes of distillation and purification. It contains phenols, cresols, and higher homologues. Coal-tar creosote, sometimes called creosote oil, contains that portion of the distillate from coal-tar intermediate between crude naphtha on the one hand and pitch on the other. Coal-tar creosote contains phenols, cresols, and higher phenoloid bodies, also naphthalene and other solid hydrocarbons, as well as pyridin and other bodies of basic character. Creosotes vary in composition, and owe their germicidal properties to the phenol and cresols which they contain. They are seldom used as such, but form bases of many commercial disinfectants after purification or the addition of alkalies or soaps. It is the creosote from coal-tar, and not wood-tar, that is used as a germicide in public health work.

Hale<sup>10</sup> has shown that the coal-tar disinfectants of the phenoloid group are considerably less toxic than either phenol or the cresols, but they are not harmless, nonpoisonous substances as sometimes indicated by the commercial labels. On an average the disinfectants of the phenoloid group have a toxicity equal to about 15 or 20 per cent. of that of phenol.

There appears to be an intimate relation between the germicidal powers of phenol and its derivatives and their protein precipitating capacity. Many of the various halogen derivatives of phenol are highly germicidal against bacteria suspended in water, but are not particularly active in the presence of blood serum or other protein matter.

**Carbolic Acid.**—Carbolic acid is a very useful disinfecting substance with a wide range of application. It should not be depended upon to kill spores. As it does not coagulate albuminous matter as actively as corrosive sublimate it may be used for the disinfection of soiled clothing and bedding, as well as for excreta and sputum.

Carbolic acid is a popular term for an ill-defined mixture consisting largely of phenol and phenolic bodies. Crude carbolic acid was discovered by Runge (1834) in coal-tar. It is a nearly colorless, or reddish to reddish-brown liquid, turning darker on exposure to air and light. It has a strong creosote-like odor, with benumbing, blanching, and caustic effects upon the skin and mucous membrane. Crude carbolic acid is a mixture of phenols and cresols, with coloring matter and impurities. Carbolic acid is often used as a synonym for phenol; in fact, the British Pharmacopeia recognizes the name "Acidum carbolicum," but uses "phenol" as the English name for this substance. In America the term "carbolic acid" should be restricted to the crude mixture of phenols and cresols; whereas phenol is a definite chemical substance  $C_6H_5OH$ . See Phenol.

Crude carbolic acid is soluble in 15 parts of water at 15° C., making about a 6 per cent. solution. The undissolved portion should not ex-

<sup>10</sup> *Hyg. Lab. Bull.* No. 88.—U. S. P. H. S., 1913.

ceed 10 per cent. of the volume of the carbolic acid.\* Carbolic acid is a very useful disinfecting substance with a wide range of applicability. The cresols contained in carbolic acid have a higher germicidal value than pure phenol itself. The commercial carbolic acid also contains hydrocarbons, and other impurities of tar oil which are totally lacking in bactericidal properties.

Crude carbolic acid dissolves in water with some difficulty and should therefore be thoroughly mixed. It is used in solutions of 2.5 to 5 per cent., in which strength it may be used for the destruction of non-spore-bearing bacteria. A 5 per cent. solution is not dependable against spores. Warm or hot solutions are much more effective than cold. It should be remembered that crude carbolic acid (coefficient 2.75) has a higher germicidal potency than pure phenol (coefficient 1.0). Crude carbolic acid is commonly used for rough disinfecting purposes, such as floors, stables, barns, outhouses, animal pens, etc.

**Phenol.**—Phenol,  $C_6H_5OH$ , has the chemical structure of an alcohol, and is the chief constituent of carbolic acid. Pure phenol crystallizes in long colorless needles; commercial phenol forms a crystalline mass which turns reddish in time, and in contact with moist air deliquesces to a brown liquid. It has a penetrating odor and strong burning taste, and is a corrosive poison. It is soluble in 10.6 parts of water at 25° C., very soluble in ether, alcohol, chloroform, benzin, carbon disulphid, glycerin, fixed and volatile oils.

Phenol when dissolved in alcohol or ether loses in germicidal value; the addition of 0.5 per cent. of hydrochloric acid aids its activity.

McClintock and Ferry<sup>11</sup> have shown that the large majority of the coal-tar disinfectants (carbolic acid, cresols, and the like) do not destroy the virulence of vaccine virus in one-half per cent. solutions at five hours' exposure, while with this strength and length of time these disinfectants would destroy practically all non-spore-bearing bacteria. The inference, therefore, is allowable that this class of disinfectants is not safe to use for such diseases as smallpox or any other, the cause of which is not known.

The fact that carbolic acid and phenol do not actively coagulate albuminous matter renders them suitable to the disinfection of excreta and organic matters generally. They are not destructive to fabrics, colors, metals, or wood in the strengths used, and therefore may be employed for the disinfection of a great variety of objects. Crude carbolic acid, although it has a stronger germicidal power than pure phenol, has the disadvantage of having a more pungent and penetrating odor and leaves a deposit of coal-tar oils and other impurities.

<sup>11</sup> McClintock, Chas. T., and Ferry, N. S.: "The Resistance of Smallpox Vaccine to the Coal Tar Disinfectants," *Jour. of the Am. Pub. Health Assn.*, Vol. I, No. 6, June, 1911, pp. 418-420.

There has been much disparagement of phenol because laboratory tests have clearly demonstrated that it cannot always be depended upon to kill spores.<sup>12</sup> This limits but does not destroy its usefulness, especially as the great majority of the epidemic diseases of man are due to non-spore-bearing bacteria.

Spores are killed with certainty by boiling for thirty minutes in three to five per cent. phenol or some similar disinfectant.

The time of exposure to a three or five per cent. solution should be not less than one-half hour. Fabrics are usually immersed for one hour.

The introduction of a halogen atom into the benzol ring greatly increases the germicidal power of the phenols, cresols and naphthols, while at the same time the toxicity of these substances is diminished. Thus Bechhold and Ehrlich<sup>13</sup> have shown that tri-brom- $\beta$ -naphthol and tri-chlor- $\beta$ -naphthol are very powerful germicides, but practically odorless, and not very poisonous.

**The Cresols.**—By far the majority of the disinfectants sold to the public are mixtures of varying quantities of phenolic bodies, especially the cresols, with inert tar oils and an emulsifying agent such as soap or tar, and sometimes rosin, gelatin, or dextrin. These substances all possess a smell distinctive of carbolic acid and are effective germicides. The cresols,  $C_6H_4(CH_3)OH$ , have the advantage over carbolic acid or pure phenol in that they readily form beautiful emulsions, have a higher germicidal value, and are less poisonous. It has already been pointed out that while emulsions may be more potent germicides than solutions, on the other hand they lack the power of penetration.

*Cresol* is prepared from coal-tar by collecting the distillates coming over between  $140^\circ C.$  and  $220^\circ C.$ , and then purifying these distillates by treatment with solution of sodium hydroxid and hydrochloric acid. Cresol is a mixture of the three isomeric cresols obtained from coal-tar and freed from phenol, hydrocarbons, and water. It is also known as cresylic acid.

Cresol<sup>14</sup> consists of a mixture of ortho-, meta-, and para-cresols. Meta-cresol is a liquid; the other two are solid crystalline bodies having a low melting point. These cresols are found in commercial carbolic acid. The cresol group forms the next higher homologue to phenol, one atom of hydrogen being replaced in the latter by the methyl radical,  $CH_3$ . The cresols are very insoluble in water. Their solution may be facilitated by the use of alcohol or glycerin. Cresol is a clear or pink-colored

<sup>12</sup> Anthrax spores are remarkably resistant to phenol solutions, and may be viable after four days' immersion in a five per cent. solution.

<sup>13</sup> Bechhold, H.: *Ztschr. f. Hyg. u. Infektionskrankh.*, 1909, Bd. 64, p. 113. Bechhold, H. and Ehrlich, P.: *Hoppe-Seyler's Ztschr. f. physiol. Chem.*, 1906, Bd. XLVII, Hefte 2 und 3, p. 173.

<sup>14</sup> *Trikresol* is a trade name. It is the same substance as "Cresol" of the U. S. Pharmacopeia.

syrupe liquid. It is soluble to the extent of about  $2\frac{1}{2}$  per cent. in water. It is somewhat less poisonous than carbolic acid; its uses are the same. It is an effective germicide in a 1 per cent. solution, which is as active as 3 per cent. phenol.

**Liquor Cresolis Compositus.**—Liquor cresolis compositus of the U. S. Pharmacopeia is a substitution compound for lysol and consists of cresol, 500 gm.; linseed oil, 350 gm.; potassium hydroxid, 80 gm.; and water sufficient to make 1,000 gm. This official mixture makes a clear solution in water. The solution is intended as a substitute for the many commercial preparations of cresol on the market. It has practically the same uses as lysol.

**Lysol.**—Lysol is a brown, oily-looking, clear liquid with a creosote-like odor. It is made by dissolving a fraction of tar oil which boils between  $190^{\circ}$  and  $200^{\circ}$  C. in fat, and subsequently saponifying by the addition of alkali in the presence of alcohol. It contains 50 per cent. cresols, especially meta- and para-cresols, and 50 per cent. of a strong concentrated potassium soap made with linseed oil. The soap contains 68 per cent. of fatty acids. Lysol is miscible with water, forming a clean saponaceous, frothy liquid. It is more powerful as a germicide than phenol, and is usually used in 1 per cent. solution. It has a carbolic coefficient of 2.12 without organic matter and 1.87 with organic matter.

*Pyxol* is a preparation of cresol and soft soap analogous to lysol.

**Creolin.**—Creolin is a preparation similar to lysol. It is a proprietary preparation patented by Pearson and consists of an emulsion of cresols and certain other products contained in tar oil, with rosin soap. Many other similar preparations are on the market, such as cresolin, cyllin, disinfector, sanator, izal, creosapol, sylphonathol, etc. The tar oil is brought into solution either with rosin soap or by means of concentrated sulphuric acid. Creolin forms a milky emulsion when mixed with water. It is used in 1 or 2 per cent. solution. The phenol coefficient is 3.25 without organic matter and 2.52 with organic matter.

**Aseptol.**—Aseptol is a 33 1-3 per cent. watery solution of orthophenolsulphonic acid,  $C_6H_4(SO_3H)OH$ . It is made by mixing equal parts of phenol and concentrated sulphuric acid in the cold; if warmed, parasulphonic acid is formed, which is a much feeble germicide than orthosulphonic acid. The acidity of the orthophenolsulphonic acid is neutralized with barium carbonate.

Aseptol is a colorless liquid which gradually turns yellowish when exposed to the light, with a weak odor of phenol, and a feeble acid reaction. It is miscible, in all proportions, with water, alcohol and glycerin. Orthophenolsulphonic acid gradually changes to paraphenolsulphuric acid in watery solution. Aseptol is much used in Germany for the disinfection of barns, outhouses, stables, and woodwork, soil, and the purifi-

cation of rough substances generally. It is usually used in 5 per cent. solution. In this strength it will kill anthrax spores in 24 hours.

**Asaprol.**—Asaprol is the calcium salt of  $\beta$ -naphthol sulphonic acid. It is made by warming 10 parts of  $\beta$ -naphthol with 8 parts of concentrated sulphuric acid in a waterbath until a clear solution is obtained. It is then diluted with water, neutralized with calcium carbonate, filtered, and the filtrate dried to a reddish powder. This powder is soluble in  $1\frac{1}{2}$  parts of water and 3 parts of alcohol. It turns blue upon the addition of ferric chlorid.

**Sanatol.**—Sanatol is a dark fluid, readily miscible with water, forming a slight turbidity. It is made from 20 parts of tar oil, containing phenols, and 10 parts of 90 per cent. sulphuric acid, and diluted with water sufficient to make 100 parts.

**Solveol and Solutol.**—Solveol is a solution of sodium cresolate in excess of cresol. Solutol is a solution of cresol in excess of sodium cresolate.

There are a vast number of other commercial disinfectants of similar nature consisting of coal-tar creosotes in combination with alkalies, soaps, resins, etc., such as chloronaphtholeum, sylphonathol, bacillol, saprol, paracresol, and other trade names.

**Naphthols.**—Naphthols are found in coal tar though in small amount. They have a high germicidal value about the equal of phenols. Naphthol,  $C_{10}H_7OH$ , is a hydroxyl derivative of naphthalene;  $\alpha$  and  $\beta$  modifications are known. The latter is of especial interest as a germicide. Naphthol itself is insoluble in water, but may be rendered soluble as a sodium salt, or may be emulsified with soaps or resin. Naphthol is used more as a medicinal germicide than in public health work. Tri-chlor- $\beta$ -naphthol is much more germicidal, but less toxic than phenol.<sup>15</sup>

**Ambrine.**—Ambrine is a mixture used in the treatment of burns. It is a proprietary preparation, and similar to a product made according to the following formula:  $\beta$ -naphthol, 0.25 per cent.; eucalyptus oil, 2 per cent.; olive oil, 5 per cent.; hard paraffin, 25 per cent.; and soft paraffin, 67.75 per cent.

**Naphthalene.**—Naphthalene,  $C_{10}H_8$ , is a hydrocarbon obtained from coal tar and purified by crystallization. It is a white, shining crystalline substance, having a strong characteristic odor resembling coal tar, and a burning aromatic taste. It slowly volatilizes on exposure to air. Naphthalene is insoluble in water, but soluble in alcohol. It burns with a smoky flame.

Naphthalene has antiseptic properties but is much less active than either the cresols or the phenols. It is poisonous to most fungi and probably to most insects. Under the name "tar camphor" it has largely sup-

<sup>15</sup> See "Phenol und seine Derivate als Desinfektionsmittel," by Kurt Laubheimer. Urban and Schwarzenberg, Berlin, 1909.

planted true camphor as a means of preventing the deposition by moths of eggs in woolen clothing.

## FORMALIN

**Formalin.**—Formaldehyd in solution is known as formalin. This is a very valuable disinfectant with a wide range of usefulness in general practice. It is superior to bichlorid of mercury for many purposes, especially as its action is not seriously retarded by the presence of albuminous matter. Formalin is not injurious to most articles, and it is not very poisonous. It is a true deodorant.

Formalin consists of a 40 per cent. solution of the gas formaldehyd ( $\text{HCHO}$ ) dissolved in water. The liquid is a clear solution, giving off an appreciable odor of the gas. It is exceedingly irritating, but not especially toxic. Formalin solutions are rather unstable. There is a constant loss by evaporation if the liquid is not kept well corked, and in cold weather the formaldehyd polymerizes and precipitates in one of its polymeric forms—trioxymethylene. For the description and discussion of formaldehyd see page 1391.

Hot formalin attacks iron and steel, but in the cold has no appreciable effect. It does not attack copper, brass, nickel, zinc, and other metal substances. It causes no diminution in strength of textile fabrics and has no bleaching or other deleterious effects upon colors. Formalin renders leather, furs, and skins brittle as a result of the union that takes place between the formaldehyd and the organic matter of these articles, and they should therefore be disinfected by another process.

A 10 per cent. solution of formalin in water is about the equivalent of a 1 to 500 solution of bichlorid of mercury, or superior to a 5 per cent. solution of carbolic acid. It must be borne in mind that in speaking of a solution of formalin a solution is meant of the liquid containing 40 per cent. formaldehyd; that is, a 1 per cent. solution of formalin would contain that liquid in proportion to 1 to 100, but would contain the substance formaldehyd in the proportion of 1 to 250.

Fecal masses are deodorized almost instantly by a small quantity of formalin, and are disinfected in a short time when intimately and thoroughly mixed with a 10 per cent. solution. It is advisable to continue the contact one hour to insure complete action.

There is some discrepancy as to the percentage of formalin solution necessary to accomplish trustworthy disinfection in general practice. Taking into account the deterioration of the solution with age and allowing an excess as an element of safety, a 10 per cent. solution is recommended. It may be used to disinfect urine, excreta, sputum, and other similar substances.

## OXIDIZING AGENTS

**Potassium Permanganate.**—Potassium permanganate is a germicide of undoubted value, but of very limited application in general practice on account of the readiness with which it is reduced and rendered inert by organic matter. Despite its limitations it ranks high on the list of germicides for certain definite purposes, more particularly in surgical practice. It has been much used in India and other places for the purification of water.

All the permanganates are strong oxidizing agents, but as soon as they are reduced to manganese salts their disinfecting action ceases, so that their maximum germicidal effects are transitory.

Potassium permanganate ( $\text{KMnO}_4$ ) is a dark purple, crystalline substance with a sweet, astringent taste. A few crystals impart to a large quantity of water a rich purple tint which is destroyed by organic matter and deoxidizing agents. It is soluble in 16 parts of cold and 2 parts of boiling water. The stain produced by potassium permanganate may be removed by a solution of oxalic acid, muriatic acid, or simple lemon juice.

Potassium permanganate readily gives up its available oxygen, and it is the free nascent oxygen that is the true disinfecting agent. Sternberg found a solution of 1 to 833 sufficient to kill pus cocci in two hours. Koch found that a 5 per cent. solution killed spores in one day. Loeffler found that the bacillus of glanders is destroyed in two minutes by a 1 per cent. solution.

Water containing organic matter may be purified to a certain extent and rendered palatable by adding, drop by drop, a solution of permanganate until the pink color of the water ceases to be destroyed after the lapse of 24 hours. The clear liquid may then be decanted and used. Permanganate used in this way does not reach sufficient concentration to be a trustworthy germicide.

**Hydrogen Peroxid and Other Peroxids.**—Hydrogen peroxid is a rather feeble germicide, but has certain other qualities which render it useful in surgical practice. Blood, pus and muscle juice contain an enzyme "catalase" which rapidly brings about the decomposition of hydrogen peroxid with the liberation of gaseous oxygen. This action rapidly decomposes all the peroxid and its disinfecting action comes to a speedy end. The mechanical effect of the disengaged gas is often a valuable property, and is made use of in loosening sticky secretions, washing away pus, or loosening adherent dressings.

Other very active oxidizing agents used as germicidal agents are ozone (page 869) and hypochlorites (page 1132).

## LIME

Lime is one of the best and cheapest disinfecting substances we have. It is usually used either as lime or chlorinated lime.

Lime, or quicklime, is a very caustic substance used for the destruction of organic matter as well as germ life. On account of its efficiency and cheapness it is a valuable addition to the list of practical disinfectants. Lime or calcium oxid ( $\text{CaO}$ ) is one of the alkaline earths. It is not so caustic as the alkalis, having less affinity for water. It is obtained by calcining native calcium carbonate ( $\text{CaCO}_3$ ), such as chalk, limestone, or marble, by which the carbon dioxid is driven off and the calcium oxid remains behind. Lime as such requires the addition of water for germicidal purposes.

**Slaked Lime.**—Slaked lime or calcium hydroxid,  $\text{Ca}(\text{OH})_2$ , is prepared by adding one pint of water to two pounds of lime. The lime absorbs about half its weight of water. The mass becomes heated and the air escapes from the pores of the lime with a hissing noise. The result is calcium hydroxid or slaked lime. Upon exposure to the air the slaked lime will absorb still more water and also carbon dioxid, converting it into calcium carbonate, which is inert so far as its disinfecting power is concerned. Freshly slaked lime should therefore always be used.

*Whitewash* is slaked lime mixed with water. It is commonly used for the disinfection, sweetening, and brightening of the walls of cellars, rooms, barracks, barns, stables, poultry-houses, and out-buildings generally. Whitewash is a very satisfactory method of destroying spore-free bacteria that may have lodged upon such surfaces. It improves illumination and is an incentive to keep things clean. A mordant such as glue is usually added to whitewash to make it adhere; also a little bluing.

*Milk of lime* is slaked lime mixed with four to eight times its volume of water to the consistency of a thick cream. It is useful for the disinfection of excreta and privy vaults. Air-slaked lime containing the inert carbonate must not be used in the preparation of whitewash or milk of lime, freshly slaked lime containing calcium hydroxid being necessary to accomplish disinfection. Calcium hydrate is mostly insoluble and settles to the bottom; the milk of lime must therefore be agitated to restore its homogeneous character before it is used. Milk of lime is most powerful when freshly prepared. It soon changes to the inert carbonate, and therefore should not be used if more than a few days old unless carefully protected from contact with the air.

Almost all laboratory experiments, while differing somewhat in certain unimportant particulars, confirm the conclusions of the early investigators as to the great practical value of lime as a germicide. A 1 per cent. watery solution of the hydroxid kills non-spore-bearing bac-

teria within a few hours. A 3 per cent. solution kills typhoid bacilli in one hour. A 20 per cent. solution added to equal parts of feces or other filth and mixed with them will disinfect them within one hour.

Lime is particularly valuable in the disinfection of excreta. The lime in one form or another must be well incorporated with the mass and enough must always be added in order to make the reaction of the mixture distinctly alkaline. Sternberg recommends that freshly prepared milk of lime should contain about one part by weight of hydrate of lime to eight parts of water. This should be used freshly prepared and added in quantity equal in amount to the material to be disinfected. The mixture should be allowed to stand at least two hours before final disposal. Fortunately, this valuable disinfecting agent is very cheap, so that it can be used with a liberal hand in excess of the amount which scientific tests find necessary. See page 1432.

Lime has been used since very early times in connection with the disposal of the dead. The method is an admirable one for the burial and disinfection of bodies dead from a communicable disease. The body should be placed in a tight coffin with twice its weight of fresh, unslaked lime, without the addition of water or moisture in any form.

**The Chlorin Group.**—The chlorin group of disinfectants includes a number of important substances such as chlorin itself, hypochlorous acid and its sodium and calcium salts, and organic "chloramins," that is, substances containing chlorin attached to nitrogen in the form of NCl groups. They are all characterized by marked instability, since in disinfection they react not only with the cell constituents of microorganisms, but also with most other substances which are apt to accompany bacteria. In so reacting, the active chlorin of the antiseptic is eventually converted either into inert chlorids or into inert organic substances in which the chlorin has become united to carbon. Thus, in using the chlorin germicides, as with hydrogen peroxid, the process of disinfection will only go on so long as some of the active substance remains undecomposed. The action is rapid and transitory.

**Bromin and Iodin.**—Bromin and iodine are very potent germicides. They have about the same value as chlorin, both in their gaseous state and in solution. The tincture of iodine is now much used in surgery for the disinfection of the skin. The use of iodine as a skin disinfectant introduced by Stretton,<sup>16</sup> in 1909, has great value for this purpose. A 2½ per cent. solution is usually strong enough and alcohol is the best solvent. Seventy per cent. alcohol is preferable to stronger spirit, and it is important to use pure alcohol, as otherwise iodo-acetone and other products are apt to be formed, which are very irritating.

**Chlorinated Lime** (Chlorid of Lime).—Chlorinated lime was used as a disinfectant and deodorant long before bacteriology was a

<sup>16</sup> *Brit. Med. Journ.*, Aug. 14, 1909; also May 22, 1915.

science. The early work of Sternberg demonstrated that the confidence placed in this substance from an empiric standpoint is justified by scientific tests. Chlorinated lime under certain circumstances, in fact, is one of the most powerful germicides we possess, and has been used particularly for the disinfection of water and sewage. See page 1209.

Chlorinated lime, popularly miscalled chlorid of lime, is a soft, white, friable substance, and is known also as bleaching powder. It has a peculiar chemical composition and is somewhat unstable. It is made by passing chlorin gas through lime. Owing to its affinity for moisture, which it slowly absorbs from the air, it soon becomes pasty and loses some of its chlorin; the hypochlorites are reduced to chlorids, which are inert as germicides. Freshly prepared chlorinated lime should have a very slight odor of free chlorin. A strong odor of this gas indicates that deterioration of the substance is taking place. It should therefore be kept in air-tight receptacles.

Chlorinated lime is made by passing nascent chlorin gas over very slightly moist calcium hydroxid. Concerning its exact chemical composition there is some disagreement. It is represented by the formula  $\text{CaOCl}_2$  or  $\text{ClCaOCl}$  or  $\text{Ca}(\text{ClO})\text{Cl}$ . The dry powder contains calcium oxychlorid ( $\text{CaOCl}_2$ ), which is at once converted into calcium hypochlorite ( $\text{Ca}(\text{OCl})_2$ ) and calcium chlorid ( $\text{CaCl}_2$ ) in watery solution; thus:  $2\text{CaOCl}_2 = \text{Ca}(\text{OCl})_2 + \text{CaCl}_2$ .

According to the U. S. Pharmacopeia it should contain not less than 35 per cent. of available chlorin. The British standard is 33 per cent. and the German 25 per cent. Chlorinated soda has almost the same germicidal value as chlorinated lime. Chlorinated soda is sold in solution, and is prepared by mixing a solution of chlorinated lime and sodium carbonate.

Chlorinated lime is only partially soluble in water or in alcohol. A solution in water of 0.5 to 1 per cent. will kill most bacteria in from one to five minutes. A 5 per cent. solution usually destroys spores within an hour.

The action of bleaching powder depends upon at least three factors:

(1) *Nascent oxygen*, which is formed by the breaking down of hypochlorous acid, is a very potent germicide:

This is perhaps one of the chief effects, and therefore the action of bleaching powder is not so much a process of chlorination as one of oxidation.

(2) *Chlorin gas*, which is a very powerful germicide. Some of it exists free in the bleaching powder and some of it is formed by the decomposition of hypochlorous acid and also of hypochlorites in acid solution: thus,  $2\text{HOCl} = \text{H}_2\text{O} + \text{Cl} + \text{O}$ .

(3) *Chloramins* contain the radical  $\text{NCl}$ , and are formed by the union of chlorin and its compounds with ammonia and amino-acids. Most chloramins are strong germicides; some of them have extraordinary activity. See page 1134.

In addition, the hypochlorites themselves are probably directly poisonous to bacteria without intermediate chemical action.

Chlorinated lime not only bleaches but is destructive to fabrics. If the solution is employed for the disinfection of body linen and washable clothing these articles must, after a not too long immersion, be thoroughly washed in plenty of fresh water.

It should be remembered that the hypochlorites are decomposed and practically rendered inert by organic matter. They should therefore be used largely in excess. Thus a preparation containing 10 per cent. of available chlorin has the high carbolic coefficient of 21.0, but on mixing an equal amount of this preparation with urine and allowing the mixture to stand one hour the coefficient falls to 0.8 per cent. (Klein<sup>17</sup>). Gruber points out that the efficiency of chlorinated lime, when used to disinfect cattle wagons, is greatly increased by first thoroughly washing away the organic matter.

Chlorinated lime may be used either as a dry powder or in solution. As a dry powder it is very generally used by strewing it into damp corners of cellars, privies, and similar places, where it acts as a deodorant and desiccant and retards the growth of mold. The dry substance may also be used to disinfect excreta. For this purpose enough of the chlorinated lime must be added and well incorporated with the mass and sufficient water added to make a 4 or 5 per cent. solution. Much more chlorinated lime is necessary to disinfect feces in a bed-pan than for sewage.

In the U. S. Army a 4 per cent. strength of chlorinated lime in solution is officially prescribed for use in the disinfection of the excreta of the sick, it being specifically stated that the chlorinated lime so used shall be of good quality and not have undergone decomposition. A solution known as the "American standard," containing 6 ounces of the powder to the gallon, is largely used for the disinfection of discharges and for the scrubbing of floors and other surfaces.

In recent years chlorinated lime or chlorinated soda has come into special prominence on account of its use for the disinfection of drinking water. A surprisingly minute amount will disinfect a large volume of water. The amount required depends upon the quantity of organic matter contained in the water. A clean water may be rendered safe by the addition of 0.1 of a part of chlorinated lime (estimated as available chlorin) to 1,000,000 parts of water. For waters containing organic

<sup>17</sup> *Public Health*, Oct., 1906. Confirmed by Rideal, Sommerville, Moore, and others.

matter as much as 1 to 5 parts per 1,000,000 may be required. See page 1132.

Chlorinated lime may also be used to advantage to disinfect the bath water in cases of typhoid fever, dysentery, cholera, or other communicable diseases. It may also be used for the disinfection of springs, wells, cisterns, tanks, and many other purposes. See page 1138.

For campers and travelers a convenient method for using chlorinated lime to disinfect drinking water is to add 1 gram of chlorinated lime containing approximately 30 per cent. of available chlorin to 1 liter of water. This should be mixed thoroughly and enough of the mixture added to the water in question to make 1 part of chlorinated lime to 200,000 parts of water, and then allowed to stand at least 20 minutes after having been thoroughly shaken. The water may then be regarded as safe, so far as typhoid, cholera, and similar infections are concerned. A solution may be prepared by adding half a teaspoonful of chlorinated lime to a pint of water. Use a teaspoonful of this to 10 gallons; 36 drops to 1 gallon; or 9 drops to 1 quart. Let stand at least 15 minutes. Halozone tablets may be used (if fresh). See page 1134.

Javelle water consists of chlorinated potash, 65 grams; chlorinated lime, 90 grams; water sufficient to make 1,000 grams. It is used as a medicinal wash.

*Labarraque's Solution.*—Labarraque's solution is an aqueous solution of several chlorin compounds, chiefly sodium hypochlorite ( $\text{NaClO}$ ) and sodium chlorid ( $\text{NaCl}$ ), and should contain at least 2.6 per cent. by weight of available chlorin as determined by titration with thiosulphate. The solution is clear and colorless when pure. If prepared with an excess of chlorin it is yellowish in color. It has a feeble odor of chlorin and bleaches indigo, litmus, and vegetable dyes. In practice this solution diluted with water 1 to 4 is mainly used for the disinfection of the person, and in surgery, but as it is more expensive and somewhat less efficient than chlorinated lime it has no advantages over that substance.

*Dakin's Solution.*—Dakin's solution came to notice during the World War in the Carrell method of treating wounds. It may be looked upon as an improved Labarraque's solution. The active ingredient of Dakin's solution is sodium hypochlorite. It must be freshly prepared; must have an entire absence of caustic alkali; the concentration must be exactly between 0.4 and 0.5 per cent. Below 0.4 per cent. of hypochlorite, the solution is not sufficiently active, and above 0.5 per cent. it becomes irritating.

Dakin's solution is made from chlorinated lime, anhydrous sodium carbonate and sodium bicarbonate. The method of preparation and testing is given by Dakin and Dunham,<sup>18</sup> and also by Carrell.<sup>19</sup>

<sup>18</sup> "Handbook of Antiseptics," Dakin and Dunham.

<sup>19</sup> *J. A. M. A.*, LXVII, 24, Dec. 9, 1916, p. 1777.

For *dichloramin-T*, *halazone* and other chlorin compounds, see page 1134.

**Antiformin.**—Antiformin is the patented name of a disinfectant which was introduced in 1900 by Victor Tornell and Axel Sjöo of Stockholm as a cleansing material for fermenting vats in breweries, but it is only since the investigations of Uhlenhuth and Nylander<sup>29</sup> in 1908 that it has come into prominence in bacteriological and sanitary work.

Antiformin consists of equal parts of liquor sodae chlorinatae of the British Pharmacopeia and a 15 per cent. solution of caustic soda. The formula for the liquor sodae chlorinatae is as follows:

Sodium carbonate .....	600
Chlorinated lime .....	400
Distilled water .....	4,000

Dissolve the sodium carbonate in 1,000 c. c. of the distilled water; triturate thoroughly the chlorinated lime in the remainder of the water; filter; mix the two and filter again.

Antiformin has a strong germicidal action in weak solutions (2 to 5 per cent.), killing ordinary cocci and some bacilli rapidly, five minutes at most being sufficient. In this respect antiformin acts more rapidly and surely than either of its component parts used alone. It has, however, very slight action upon the tubercle bacillus, the smegma bacillus, and other organisms belonging to the acid-fast group.

Antiformin is an almost colorless liquid, with a strong odor of chlorin, and is strongly alkaline. It keeps fairly well without particular precautions being taken. It has deep powers of penetration, owing to its ability to dissolve and render homogeneous the various substances in which bacteria are often found, such as sputum, feces, pus, urinary sediment, and even small pieces of tissue.

The germicidal action of antiformin is doubtless due to the energetic oxidizing properties of the chlorinated lime. The fact that it does not kill the tubercle bacillus and other acid-fast organisms seems to be due to the biochemical nature of these bacilli. The fatty or waxy capsule which is present and which gives them their acid-fast property acts as an impervious coat, resisting the dissolving action of the antiformin, and so protects the protoplasm of the bacilli from its germicidal action. The tubercle bacillus may be isolated in pure culture by exposing tuberculous sputum to a 20 per cent. solution of antiformin for 24 hours at room temperature or 4 to 6 hours at incubator temperature. The bacilli may then be thrown down by centrifugalization, washed free of alkali, and then planted upon solidified egg or other suitable culture medium, or injected into susceptible animals.

<sup>29</sup> *Berl. klin. Wochenschr.*, LXV, No. 29, July 20, 1908.

While antiformin is therefore a very active germicide for the ordinary bacteria it cannot be depended upon for the acid-fast group.<sup>21</sup>

**Dyestuffs.**—A large number of dyestuffs possess germicidal properties, although until recently they have been employed for the destruction of blood parasites, such as trypanosomes, rather than bacteria. Many germicidal dyes are selective or specific in action.

Malachite green, used in conjunction with mercuric chlorid, is used extensively, especially in naval service. Certain other dyes chemically related to malachite green (triphenylmethanes) possess definite bactericidal action, as hexamethyl violet—also known as crystal violet—hexethyl violet and brilliant green.

*Acriflavine, trypaflavine, or flavine*, was first prepared by Benda<sup>22</sup> at Ehrlich's instigation in 1911, and was found to have marked germicidal action on trypanosomes. Acriflavine has been claimed by Brown-ing and his associates<sup>23</sup> to be a most powerful germicide. It is used in surgery and has also been employed in the disinfection of the nasopharynx of carriers of the meningococcus. Dakin and Dunham<sup>24</sup> regard acriflavine as distinctly more active under most conditions than either malachite green or brilliant green, though its rate of disinfection is decidedly slow. One of the most remarkable properties of acriflavine is that its germicidal action is apparently enhanced by admixture with serum, though greatly diminished by pus.

## ACIDS

Acids in sufficient concentration are very effective germicides. An amount of acid which equals 4 per cent. of normal hydrochloric acid is sufficient to prevent the growth of all kinds of bacteria and to kill many.

The germicidal power of an acid depends upon the free hydrogen ion in solution. The disinfecting power of an acid is therefore proportional to the hydrogen ion concentration, and this in turn is proportional to the dissociation of the acid. Thus, when we speak of a strong acid, we mean one that is highly dissociated, and, conversely, a weak acid one which is slightly dissociated. The mineral acids are more corrosive and also more germicidal than the organic acids because they have higher hydrogen ion concentrations. A 1 to 500 solution of sulphuric acid kills typhoid bacilli within one hour. Hydrochloric acid is about one-third weaker, and acetic acid weaker still. Citric, tartaric, malic, formic, and salicylic acids are about equal to acetic acid. Boric acid

<sup>21</sup> Paterson, R. C.: "A Report on the Use of 'Antiformin' for the Detection of Tubercle Bacilli in Sputum, etc.," *Jour. of Med. Research*, Vol. XXII, No. 2, April, 1910, p. 315.

<sup>22</sup> *Berl. Deutsch. Chem. Gesell.*, 45, p. 1787, 1912.

<sup>23</sup> *Brit. Med. Journ.*, Jan. 20, 1917, p. 73.

<sup>24</sup> "Handbook of Antiseptics," p. 64.

is very feeble; it destroys the less resistant bacteria in 2 per cent. solution and inhibits the others.

## ALCOHOL

Alcohol has both antiseptic and germicidal properties. In solutions of 1-1.000 the growth of some bacteria is somewhat delayed. Many microorganisms grow abundantly in 40 per cent. alcohol and some in stronger solutions. Dry bacteria may be exposed to absolute alcohol for 24 hours without losing their vitality, while 60 to 70 per cent. alcohol has definite germicidal power to both dry and moist microorganisms. The explanation of this curious phenomenon seems to be that alcohol fails to penetrate the microbe unless in the presence of water. Under 40 per cent. the germicidal action is very slow so that the limits of alcohol as a disinfectant may be placed between 50 and 70 per cent. In this strength it is equivalent to about 3 per cent. carbolic acid provided there is little or no albuminous matter present.

Dakin and Dunham found that most vegetative forms of bacteria may be killed fairly readily by 50 per cent. alcohol, but that much higher or lower strengths are less effective, while most spores are unaffected by alcohol of any strength.

Alcohol precipitates protein which therefore seriously interferes with its germicidal property. Many germicidal substances which are potent when dissolved in water, have comparatively little effect when dissolved in strong alcohol.

Krönig and Paul found that phenol dissolved in 98 per cent. alcohol was devoid of bactericidal action when tested against spores. It is therefore clear that alcohol is not a desirable solvent for phenolic disinfectants.

## BORATES, PERBORATES AND BORIC ACID

These substances possess almost negligible germicidal properties, and are used as mild disinfectants in medicinal washes, and as antiseptics for preserving foods.

## ETHER AND CHLOROFORM

The vapors of both ether and chloroform possess slight but definite action. An exposure to ether vapors of one to forty-eight hours was necessary to sterilize agar slants on which pyogenic organisms were growing.<sup>25</sup> Ether is irregular in its action, for good contact with the organisms is difficult to secure. Chloroform is sometimes used as an antiseptic to preserve antitoxic serums.

<sup>25</sup> Topley, *Brit. Med. Journ.*, Feb. 6, 1915.

## SOAPS

Ordinary soaps have but limited disinfecting power. According to Behring the germicidal power of soaps depends upon their alkalinity, but Serafini more correctly points out that the free alkali present, even in concentrated soap solutions, is so small in amount that it can exert no disinfecting action whatever, and that neither the alkali nor the fatty acid, nor the combination of the two is the effective agent.

Unfortunately, the disinfecting power of soap solutions is not marked enough to make them trustworthy disinfectants despite their great value as detergents. The common commercial soaps, especially the colored soaps, are frequently of very poor quality, containing rosin instead of fat, and are not to be depended upon. The soft soaps should also be avoided on account of the presence of all the impurities of the fat and alkali from which they are made. There are other conditions which render the use of soaps uncertain, the chief of which is the hardness of the water.

The action of soap solutions is much influenced by the temperature, which is easy to understand when we recall the powerful germicidal action of hot water alone. It has been shown that soap, even in strong solution and with prolonged exposure, cannot be trusted to destroy the infection of typhoid, cholera, or the micrococci of suppuration. Therefore soaps alone cannot be depended upon for the disinfection of objects and clothing, but in conjunction with certain compatible chemicals, and also with the mechanical cleansing which always accompanies their application, soaps have a wide and varied usefulness in sanitation.

Soap solutions should always be made with soft water. The addition of one of the caustic alkalies, as lye, increases their germicidal and detergent value. The solution should be strong, containing not less than 10 per cent. of soap, and the water should be as hot as possible and applied with mops or brushes.

Medicated soaps are for the most part a snare and delusion so far as any increased germicidal action is concerned. In fact, the addition of carbolic acid, bichlorid of mercury, and other substances which have the property of combining chemically with the soap seems actually to diminish the disinfecting value of the substance. As a rule a very small quantity of the disinfecting substance is added to the soap, and when we call to mind what an exceedingly small quantity of soap is generally used for the ordinary washing of the skin and the further dilution of this small amount by the water used it is easy to understand that medicated soaps as ordinarily applied cannot have an energetic disinfecting action.

An exception seems to be the soap devised by McClintock, in which a mercury salt exists unchanged and active. He found that double iodid of mercury answers this purpose in the proportion of 0.05 to 2 per cent. A solution containing 1 per cent. of the soap was found by him to be fatal to pus cocci, cholera, diphtheria, and typhoid bacilli in one minute. This soap does not attack nickel, silver, aluminium, steel instruments, or lead pipes, and does not coagulate albumin.

The value of soap consists in the removal rather than the milling of germs; that is, the cleansing properties are more important than the germicidal action. In hand washing, all the bacteria are not removed by soap and water. Therefore, an active germicide must be used in addition in order to render infected hands safe.

**Comparative Germicidal Values.**—The following is a table of comparative germicidal values taken from Park:

TABLES OF GERMICIDAL VALUES

Alum .....	1 : 222	Mercuric chlorid.....	1 : 14,300
Aluminium acetate.....	1 : 6,000	Mercuric iodid.....	1 : 40,000
Ammonium chlorid.....	1 : 9	Potassium bromid.....	1 : 10
Boric acid.....	1 : 143	Potassium iodid.....	1 : 10
Calcium chlorid.....	1 : 25	Potassium permanganate....	1 : 300
Calcium hypochlorite.....	1 : 1,000	Pure formaldehyd.....	1 : 25,000
Carbolic acid.....	1 : 333	Quinin sulphate.....	1 : 800
Chloral hydrate.....	1 : 107	Silver nitrate.....	1 : 12,500
Cupric sulphate.....	1 : 2,000	Sodium borate.....	1 : 14
Ferrous sulphate.....	1 : 200	Sodium chlorid.....	1 : 6
Formaldehyd (40%).....	1 : 10,000	Zinc chlorid.....	1 : 500
Hydrogen peroxid.....	1 : 20,000	Zinc sulphate.....	1 : 20

# CONVENIENT FORMULAE FOR DISINFECTING SOLUTIONS

## Bichlorid of Mercury—Corrosive Sublimate.

Bichlorid of mercury.....	1 dram		1 gram
Water .....	1 gallon		1 liter

Mix and dissolve. Label "*Poison!*" This is approximately a 1 to 1,000 solution. One ounce of this solution contains very nearly half a grain of corrosive sublimate. Useful for disinfecting clothing, the hands, the surfaces of walls, floors, furniture, etc. Not serviceable for feces or material containing much organic matter.

## Formalin.

Formalin .....	13 ounces		100 c. c.
Water .....	1 gallon		1 liter

Formalin is a watery solution containing 40 per cent. formaldehyd. The above solution contains approximately 10 per cent. of formalin and is useful for the disinfection of clothing and a great variety of objects.

As it has no corrosive action it does not bleach pigments or rot fabrics. When used to disinfect feces a stronger solution may be used.

**Milk of Lime.**—Slake a quart of freshly burnt lime, in small pieces, with three-fourths of a quart of water, or, more exactly, 50 parts of water by weight with 100 parts of lime. A dry powder of slaked lime (calcium hydroxid) results. Prepare the milk of lime shortly before it is to be used by mixing 1 quart of this dry calcium hydroxid with 4 quarts of water. Air-slaked lime is worthless. Slaked lime may be preserved some time if inclosed in an air-tight container. Milk of lime is especially useful for the disinfection of feces; an equal quantity should be added to the mass and thoroughly mixed.

#### **Carbolic Acid.**

Crude carbolic acid (or phenol) . . .	7 ounces		50 c. c.
Water . . . . .	1 gallon		1 liter

The solution is facilitated by dissolving in hot water. This makes approximately a 5 per cent. solution. The addition of from 12 to 14 ounces of common salt to each gallon increases its germicidal power, especially when used for the disinfection of excreta. The crude carbolic acid is more powerful than pure phenol, but can only be used for rough work, such as floors, feces, sputum, etc. For the disinfection of clothing phenol should be used and the solution may be mixed half and half with water, making approximately a 2½ per cent. solution.

#### **Chlorinated Lime ("Chlorid of Lime").**

Chlorinated lime . . . . .	3 ounces		30 grams
Water . . . . .	1 gallon		1 liter

Mix. This is about a 3 per cent. solution. It is exceedingly powerful and is useful for the disinfection of excreta, privy vaults, cesspools, and many other purposes. It is an active bleaching agent and destroys fabrics in this concentration.

## CHAPTER IV

### METHODS OF DISINFECTION

A few instances are given upon the following pages of the best methods of disinfecting rooms, excreta, and fomites. The examples selected have been taken as types of a class. In public health work the things most frequently needing disinfection are feces, sputum, and other discharges from the body; bed and body linen, and other fabrics; and bedrooms. The disinfection of water and the pasteurization of milk have already been considered. The disinfection of ships is described under Quarantine.

**Air.**—It is quite impossible to disinfect the air of a room during its occupancy. In fact, ordinarily little heed need be given to the air itself. Any of the known volatile substances in sufficient concentration to kill microorganisms would render the air unendurable. It is absurd to place such substances as carbolic acid, formalin, or chlorinated lime in an open pan in the sickroom or in the bathroom with the idea that they are serving a useful purpose in disinfecting the atmosphere or in preventing the spread of infection. Occasionally a deodorant, such as formalin, may be used with advantage about the room, but where proper cleanliness and ventilation are observed such substances are rarely called for.

It is of first importance to prevent the infection of the air of the room by taking precautions applicable to the particular infection in question. Thorough ventilation should be maintained, and in this way any chance infection is soon lost by dilution or killed by the sun. An open fireplace is admirable for the ventilation and purification of the air of sickrooms, for by this method the infection is not only carried away, but is destroyed by the heat of the fire in exit. The hanging of sheets wet with bichlorid of mercury or some other germicidal solution at the doorway serves no useful purpose except as a reminder to those passing in and out.

When a room has become badly infected, say from a case of pulmonary tuberculosis, and there is danger of infection through the dust, it should be given a preliminary fumigation with formaldehyd, which will partly protect the operators who have to take up the carpets or remove the bedding and other articles to the steam sterilizer.

**Rooms.**—The disinfection of a living-room calls for all the resources of the disinfectors' art. The fact that it is necessary to bring the appa-

ratus and materials to the room in order to disinfect it and its contents is one of the main difficulties and will often require the ingenuity and always the vigilance of the operator.

The method to be employed for the disinfection of a room will vary somewhat with the infection for which the disinfection is done. In routine work in the treatment of rooms liable to be infected with a variety of bacterial viruses formaldehyd gas is the most generally useful agent we possess. In the case of yellow fever or malaria insecticides must be selected; in the case of plague our efforts must be directed against rats, mice, fleas, as well as the destruction of the plague bacillus. In cholera and typhoid fever we must pay particular attention to the feces, urine and the objects soiled by them, etc.

Certain articles commonly found in living-rooms, such as bedding, carpets, rugs, cuspidors, upholstered furniture, and other objects liable to become infected must be treated separately by some process applicable to each article. None of the gaseous disinfectants can be trusted to penetrate enough to render articles of this class safe. The surest method of disinfecting a room is to remove fabrics and articles for special treatment, and to wash the floor and other surfaces with a strong hot germicidal solution. Finally, give the room a house-cleaning, sunning and airing. It may then be renovated with paper and paint.

Ordinarily carpets and rugs should be left in place until a preliminary gaseous disinfection is accomplished. They may then be taken up and removed for steam sterilization, after which they should be gone over with a vacuum cleaner and finally hung in the sun for a day or two. If carpets, rugs, upholstered furniture, mattresses, pillows, quilts, or other articles have become badly contaminated with infected discharges the soiled areas should be thoroughly saturated with a strong solution of formalin. Bedding, towels, curtains, clothing, and other articles of like nature may be left in the room exposed to the action of the gas, but should afterwards be removed for boiling, steaming, or immersion in one of the germicidal solutions, as none of the gases can be relied upon for the disinfection of fabrics. Articles removed from the room for disinfection should be placed in a bag or wrapped in a sheet wet with bichlorid of mercury. Rubbish that has collected in the room should be gathered and burned. The cuspidors and their contents require special treatment. Door knobs, bed rails and other surfaces handled by the patient or soiled with discharges should be wiped with bichlorid or carbolic solution. For the preparation of a room for fumigation, see pages 266 and 1390.

**Stables.**—The disinfection of a stable requires a particularly thorough application of all the resources at the hand of the disinfecter. The conditions met with in a stable render its disinfection doubly hard, not only on account of the accumulation of organic filth which has worked

into the many crevices and saturated the woodwork, but on account of the high resistance of anthrax and tetanus spores, for which stables are sometimes disinfected. In addition to these diseases stables require disinfection on account of tuberculosis, glanders, pleuropneumonia, foot-and-mouth disease, and various diseases of man as well as those of the domestic animals.

It is advisable to give the stable a preliminary fumigation, preferably with sulphur, in order to destroy surface infection and the vermin which always infest these places. The preliminary fumigation is especially important in the case of plague and glanders, not only to prevent the spread of the infection, but as a safeguard for the disinfectors. Then remove all small articles that need disinfection. The blankets should be wrapped in moist bichlorid sheets and boiled, steamed, or immersed in a strong germicidal solution. Buckets, currycombs, brushes, stall tools, and other equipments that have been in contact with the sick animals or with infectious materials should be mechanically cleaned with a hot carbolic solution in which they may be allowed to soak over night. Metallic and wooden objects or utensils should be given a thorough preliminary cleansing with a stiff brush and hot water and soap, and then boiled or immersed in a 5 per cent. solution of carbolic acid or 2 per cent. solution of cresol for several hours. Leather articles, as harness or equipment, should receive a similar preliminary cleansing and be scrubbed with either a strong solution of bichlorid of mercury or carbolic acid.

All hay and grain should be removed from the racks and mangers and all bedding from the floors. After its careful collection at some designated point this refuse should be saturated with petroleum and destroyed by fire.

The stable must now be soaked with a strong antiseptic solution applied with a hose or splashed on all surfaces by means of mops. The floors, corners, and stalls must be saturated with the solution. On account of the presence of so much albuminous matter carbolic acid or one of its derivatives is preferred for this purpose to chlorinated lime or sublimate solutions. Chlorinated lime is useful if used in sufficient concentration and generous amounts. Now scrape out the débris from all the cracks in the floors and walls; collect it for burning. Then clean the woodwork with hot lye or a strong alkaline soap solution and follow with another general hosing with the antiseptic liquid.

After several days' exposure to air and sunshine the interior of the stable should receive a fresh coat of whitewash, applied quickly, and prepared from freshly burnt lime.

The watering troughs are very apt to be infected, especially in dealing with glanders. In all instances not only the troughs and watering buckets should be disinfected but the water remaining in them, for

often there is no drain or sewer, and this water poured on the ground may be a source of subsequent infection. The water may first be disinfected by the addition of a suitable amount of chlorinated lime or any of the standard germicides. The troughs are then to be mechanically cleaned, thoroughly removing all organic matter, and then applying a strong germicidal solution to both the inside and outside. For metal-lined troughs the use of bichlorid of mercury is, of course, inapplicable, and for such carbolic acid, alkaline creosotes, bleaching powder or formalin is recommended. Most germicides are poisonous, and must therefore be finally washed out of the troughs or buckets by flushing with fresh water and then airing in the sunlight before they are again used. A strong carbolic, formalin, or chlorinated lime solution should be poured down all pipes and drains.

Sometimes the ground in the immediate vicinity of the stable will need attention. Lime or the gasoline torch will generally be found most useful for this purpose. Carcasses and excreta are to be disinfected and disposed of according to the methods given under these titles.

**Railroad Cars.**—Railroad cars are rooms on wheels. The principles of their disinfection present nothing novel, but the application presents practical difficulties.

Flat cars or open cars seldom need disinfection, for, even should they become infected, the exposure to the sun and weather is sufficient to render them safe from the danger of conveying disease. They may readily be disinfected whenever that may be necessary by scrubbing or flushing them with carbolic acid or bichlorid of mercury solutions.

Freight cars or box cars seldom need disinfection. They sometimes require fumigation on account of mosquitoes, fleas, or rats and mice, which such cars may carry. Freight cars are best treated for this purpose with sulphur dioxid. In actual practice it will sometimes be found useful to steam them with steam from the locomotive.

Cattle cars and cars used to transport live stock need special attention, particularly if anthrax, tetanus, glanders, foot-and-mouth disease, or tuberculosis is the infection with which they are contaminated. The disinfection of cars of this type is so much like the disinfection of a stable that it is unnecessary to repeat the description here. Cars of this type, as well as all cars, should be kept scrupulously and constantly clean.

*Day Coaches and Parlor Cars.*—If the disinfection is done as a precautionary measure it is sufficient to fill the coach with formaldehyd gas, which should be followed by a thorough mechanical cleansing. The carpets and rugs and all similar articles, including the upholstered seats and backrests, if removable, should be taken from the car for vacuum treatment and then exposed several hours to the sunshine. The floors should be mopped or scrubbed with one of the germicidal solutions and the spittoons should be well rinsed in a warm carbolic bath and the

contents disposed of in one of the ways mentioned under the heading Sputum.

If the disinfection is done on account of known contamination with one of the communicable diseases the car is treated exactly as a room would be under like conditions.

A railroad coach is likely to harbor mosquitoes, flies, and other insect pests that may carry disease; therefore precautions will have to be taken to keep these insects out of cars leaving districts infected with yellow fever, typhus fever, malaria, plague, etc., or measures will have to be taken to destroy them after they get on board. As both these requirements are difficult, if not impracticable, it will usually be found best to provide relays at a convenient point and require the passengers to change cars upon leaving an infected for an infectible area.

*Sleeping cars* present a greater difficulty than any other rolling stock. The berths are apt to become infected and the infective agent may live there a very long time, especially as they are kept closed—almost hermetically sealed, against fresh air and sunshine during the daytime. Much of the difficulty encountered in the disinfection of the sleeping car is due to peculiarities in construction, such as the compact manner in which the bedding is stowed away, the heavy and unnecessary carpets and hangings, the excessive molding and ornamentation of the older type of cars, the use of such materials as plush for upholstering, etc. The wash basins and other objects in the toilet-rooms are liable to contamination with infected discharges from the mouth and nose. The faucets should be so arranged as to permit washing with running water, thus eliminating danger from the bowl.

Before attempting to fumigate the interior of a sleeping car or a passenger coach with one of the disinfectants it is important to close the sashes and all the ventilator openings for the Pintsch gas flames. Much gas will be lost through the open hopper of the water-closet unless that is tamponed. Some cars have a system of ventilating ducts of fresh air entering under the seat or somewhere near the bottom of the car. This must be closed. Formaldehyd gas and hydrocyanic acid gas are practically the only gases which may be used for the treatment of the sleeping car. As these gases lack the power of penetration, all the berths must be opened and all the bedding and other fabric should be removed for steaming or other treatment. Hydrocyanic acid is especially serviceable for the destruction of bedbugs and vermin which frequently infest sleeping cars.

After the bedding, hangings, carpets, and other fabrics have been removed from the car the toilet-room should be given special attention. The drinking glasses, the wash basins and slabs of the washstands, the brushes and combs, the seat of the water-closet, and other objects liable to infection should be washed or immersed in one of the standard germi-

cidal solutions. An apparatus for disinfecting sewage on railway washes and vessels is described by Frank.<sup>1</sup>

**Feces.**—The disinfection of feces is most important because these discharges are most dangerous and at the same time most difficult to render safe. Fecal discharges may be disinfected with carbolic acid, cresols, lime, chlorinated lime, or formalin, as described below. In hospitals the infected discharges are sometimes boiled or charged with steam in an appropriate apparatus with the addition of a deodorizing substance, as potassium permanganate or formalin.

From patients the discharges should be received in a glass or impervious vessel containing some of the germicidal substance, more of which is added afterwards, and the mass thoroughly disintegrated and mixed. The breaking up of the masses and mixing is best done with a little stick which is then dropped into the mess. The mixture should stand at least two hours before the contents are disposed of, kept well covered meanwhile, and the vessel given a thorough cleansing and disinfection before it is again used. At least an equal quantity of the germicidal solution should be used to the mass disinfected and enough should always be added entirely to submerge all particles. Excreta must always be protected from flies and other insects, even while undergoing disinfection.

It is necessary to emphasize the importance of breaking up all masses until they are completely disintegrated, and mixing thoroughly with the germicide. It is almost impossible for any of the ordinary germicides to penetrate particles of even moderate size, within a reasonable time; emulsions do not penetrate at all, and therefore should not be used to disinfect feces.

It is always desirable to use a generous excess of germicidal agent, both as to strength and amount, in disinfecting feces. The following substances and methods are recommended:

**Lime and Hot Water.**—A simple and effective method for the disinfection of feces, such as typhoid stools, consists in adding enough hot water to cover the mass in the receptacle, and then adding about  $\frac{1}{4}$  of the entire bulk of quicklime.<sup>2</sup> A large cup of lime is about enough for an average stool. The receptacle should then be covered and allowed to stand for two hours. In addition to the germicidal action of the lime there is enough heat generated by the hydration of the lime to destroy typhoid and similar microorganisms. It is important to start with hot water from 50° to 60° C. and the mass will then be heated throughout to 80° or 90° C.

A bucket of boiling water (about 1 gallon) will disinfect a single

<sup>1</sup> P. H. Rpts., Jan. 1, 1918, Reprint No. 247.

<sup>2</sup> Linenthal, H., and Jones, H. N.: *Monthly Bull., State Bd. of Health of Mass.*, Jan., 1914, Vol. IX, No. 1, p. 50. *Boston Med. and Surg. Jour.*, Jan. 8, 1914.

stool when other germicidal agents are not obtainable. The vessel should be covered and allowed to stand until cool. Sufficient heat is thus had to destroy practically all bacteria except the spore bearers.

*Milk of Lime.*—Use freshly prepared milk of lime containing 1 part by weight of the freshly slaked lime to 4 parts of water. Add at least an equal quantity to the amount of material to be disinfected and allow the mixture to stand no less than two hours before final disposal. The perfunctory sprinkling of fecal matter with lime or milk of lime, as is often done, is not effective. Lime should not be thrown into the hoppers of water-closets for the disinfection of dejecta, for otherwise a thick mass may accumulate and obstruct the pipes. In disinfecting excreta with lime the reaction of the resulting mixture must be alkaline else the object will not be attained.

Lime or milk of lime is useful for the disinfection of privies, or trenches in camp, or in country practice. For its use under these circumstances the amount required may be arrived at as follows: The amount of fecal matter per person is reckoned at 400 grams a day. If the urine is also to be disinfected this may be counted as 1,500 to 2,000 c. c. per person daily. For the disinfection of the solid excrement alone 50 grams of lime, or 400 c. c. of the milk of lime (1 to 8), must be reckoned for each person per day. If the urine is included it will take four to five times as much. The mixture must have an alkaline reaction. Attention is again called to the fact that air slaked lime is inert.

*Chlorinated Lime.*—This is one of the most useful and potent germicidal substances for the disinfection of feces. Use at least a 3 per cent., better 5 per cent., solution and an amount at least equal to the mass to be disinfected. Thoroughly mix and allow to stand at least 2 hours. Chlorinated lime is rendered inert by organic matter; therefore an excess should always be used. It is also converted to the inert carbonate upon exposure to the air (see page 1132). Chlorinated lime may be liberally sprinkled on the fecal mass, water added, and the mixture then stirred.

*Formalin.*—A 10 per cent. solution of formalin may be depended upon to disinfect feces if thoroughly incorporated with the mass and allowed to stand at least two hours. As a deodorant it acts almost instantly.

*Carbolic Acid.*—A 5 per cent. solution of crude carbolic acid added to an equal bulk of excreta may be depended upon to disinfect in two hours, provided the germicide is thoroughly incorporated throughout the mass.

The *cresols* as “trieresol” and liquor cresolis compositus or lysol (1 or 2 per cent.) are valuable agents for the disinfection of fecal matter in small amounts on account of their energetic action and because their efficiency is not greatly impaired by the presence of albuminous matter.

*Dry earth* promotes the dehydration of excreta, thus delaying putrefactive changes while absorbing the odors. It has no inherent germicidal qualities.

*Corrosive sublimate* is not well suited for the disinfection of feces and sputum.

*Steam*.—In hospital practice, bed pans and their contents are steamed and cleaned in special apparatus. See Fig. 179.

**Sputum**.—The discharges from the mouth and nose not alone of the sick, but of well persons, are often laden with infection. This is one of

FIG. 179.—STEAM STERILIZER FOR BED PANS.

the frequent means by which disease is transferred. The proper disposal of sputum and its efficient disinfection are therefore important public health measures to check the spread of tuberculosis, diphtheria, scarlet fever, measles, whooping-cough, influenza, tonsillitis, common colds, mumps, chickenpox, cerebrospinal fever, poliomyelitis, sore throat, smallpox, pneumonia, the pneumonic form of plague, etc. It is a good rule to require the discharges from the mouth and nose of all patients to be received upon small pieces of gauze or in individual cups which may subsequently be burned.

Sputum, when in considerable quantities, should be received in paper cups, which, with their contents, may be burned. If this is not practical, it may be received in ordinary cups containing 5 per cent. carbolic solution. When not in large quantities sputum and other infective discharges should be received on cheap cloths or soft paper and promptly burned. If handkerchiefs are used they should be immersed in carbolic solution 5 per cent. for one hour before they are laundered.

The most trustworthy chemical disinfectants for sputum are carbolic acid, 5 per cent.; formalin, 10 per cent. or stronger; chlorinated lime, 5 per cent. The methods for the disinfection of sputum correspond to those described for feces. Sputum offers special difficulties on account of the mucus which is readily coagulated and hard to penetrate.

Sputum should be kept well covered in suitable receptacles until it is disposed of. Antiseptic solutions may be used in bedside cups or in cuspidors, but are not necessary.

The disinfection of the large amounts of sputum such as that collected in hospitals, public buildings, and other places is a difficult and disagreeable task. On account of its dense consistency it prevents the penetration of chemical solutions. A very good apparatus for the disinfection and disposal of sputum in hospitals, sanatoria, etc., consists of an autoclave in which the material is steamed under pressure and at a temperature of  $120^{\circ}$  C.; after the completion of the process the disinfected mass is washed through the drain into the sewer by water entering the autoclave. The entire operation can thus be conducted under cover. Dr. Wm. J. Manning<sup>3</sup> describes an ingenious and efficient method of handling spittoons and disposing of the sputum at the Government Printing Office in Washington. The cuspidors are self-draining. They are collected and handled by devices so that the attendants do not have to handle them directly.

**Bed and Body Linen.**—Fabrics, such as towels, napkins, handkerchiefs, sheets, pillowslips, underwear and similar articles, should always be disinfected after contact with any of the communicable diseases, for they are very apt to become infected. They may be steamed or boiled or immersed in a germicidal solution such as carbolic acid, 5 per cent.; formalin, 10 per cent.; or bichlorid of mercury, 1 to 1,000.

Special care is necessary in washing or disinfecting towels, sheets, underwear, and other fabrics soiled with such discharges as pus, blood, or excreta. If they are heated or boiled without special precautions they will become indelibly stained by the coagulation of the albuminous matter which becomes fixed in the fiber.

Soiled wash may be treated as follows: It is wrapped in a sheet wet with sublimate solution, and this is placed in a sack likewise moistened with a germicidal liquid. The sack is placed unopened in a solution containing 3 per cent. of soft soap and heated to  $50^{\circ}$  C. for three hours and left in the same solution for forty-eight hours after it cools. If not soiled with albuminous matter the wash may be immersed in a solution of bichlorid of mercury 1 to 1,000, with the addition of common salt. After this preliminary disinfection the articles are boiled half an hour in a water containing:

Petroleum .....	10 grams
Soft soap .....	250 "
Water .....	30 liters

**Books.**—With the exception of their exposed surface, books cannot be disinfected in the bookcase or on the shelves of houses and libraries. However, if the books have not been handled or exposed to infection in any way except by their presence in the sickroom there is no reason for considering any part of the book, except the exposed surface, as infected.

<sup>3</sup> *J. A. M. A.*, Sept. 11, 1909, Vol. LII, pp. 829-832.

Such books may be disinfected with formaldehyd gas without first disturbing them in any way.

Books which have been handled by the patient or which have been otherwise exposed to infection require particular care in their disinfection on account of the difficulty of penetrating between the leaves. Books used in public libraries are often regarded with suspicion, and many librarians require that they should be sunned, aired, or disinfected before they are again issued. The danger from this source has doubtless been exaggerated. Books, however, which have been handled by persons suffering with one of the readily communicable diseases should always be disinfected before they are again used.

Books may be disinfected in a specially constructed chamber by means of heat and formaldehyd gas. They must be arranged to stand as widely open as possible upon perforated wire trays. Under these conditions the exposure should be continued twelve hours with high percentage of formaldehyd and a temperature of 80° C., a partial vacuum having first been introduced. The binding, illustrations, and print of books are not injured by this process.

When only a few books are to be treated in the absence of a special apparatus they may be disinfected by placing 2 or 3 drops of a 40 per cent. formalin solution on every second page, taking care to distribute the drops well. The book is then laid in a close box or drawer in which more formalin has been sprinkled, and left in a warm place for not less than twenty-four hours.

Pamphlets and unbound volumes may be steamed without serious harm. Steam is not applicable to the disinfection of bound books on account of the glue and leather.

Beebe <sup>4</sup> recommends dipping the books in a solution of carbolic acid and gasoline. After immersion the books should be placed before an electric fan, which rapidly drives off the gasoline.

Nice <sup>5</sup> recommends the use of moist, hot air at 80° C. and 30 or 40 per cent. humidity for thirty-two hours for the disinfection of books. This is said to destroy all non-spore-bearing bacteria in closed books, even tubercle bacilli in thick layers, without injuring the most delicate bindings.

**Cadavers.**—Dead bodies are seldom the cause of spreading communicable diseases. The body without previous washing should be wrapped in a sheet wet with a strong germicidal solution, such as bichlorid of mercury, 1 to 500, carbolic acid, 5 per cent., or cresol, 1 per cent., until it is disposed of. Should it be desirable to wash the body it should be done with formalin (10 per cent.) or Labarraque's solution, or one of the germicidal solutions above mentioned.

<sup>4</sup>*Jour. Am. Public Health Assn.*, Vol. I, No. 1, p. 54, Jan., 1911.

<sup>5</sup>*J. A. M. A.*, April 20, 1912, Vol. LVIII, No. 16, p. 1201.

From a sanitary standpoint bodies dead of one of the communicable diseases are best disposed of by burning. When cremation is not practicable the body may be surrounded by twice its weight of freshly burnt lime in an hermetically sealed coffin and buried at least 6 feet underground. There is much less danger from the spread of disease from bodies buried in the ordinary way than is commonly supposed.

Embalming with strong solutions of formalin and arsenic that are commonly used for this purpose is effective in destroying all but the surface infection.

The disposal of bodies dead of anthrax is an important and difficult matter and has been discussed on page 402.

**Thermometers.**—A thermometer may be the source of conveying disease from one person to another, and it behooves the physician to exercise special care concerning its cleanliness and disinfection. The best practice is to keep a pure formalin or 70 per cent. alcohol in the thermometer case in which the instrument is kept constantly bathed.

**Wells and Cisterns.**—The disinfection of a well may be accomplished by the use of freshly burnt lime. About half a barrel is thrown into the well, stirred up with the water, and the walls are scrubbed down with the resulting milk of lime. The well is then pumped out, cleaned, allowed to refill, and a second supply of lime added, after which the well is allowed to stand twenty-four hours. After a thorough stirring the solution is then pumped out and the well is allowed to refill and is re-emptied until the water is practically free from lime. Instead of lime chlorinated lime may be used for this purpose, sufficient being added to make approximately a 1 per cent. solution.

## SECTION XV

### MILITARY HYGIENE

Military efficiency depends upon the health of the command. Many military disasters have been due to disease. Valor and patriotism are seriously handicapped by typhoid fever, dysentery, malaria and other infections which in years past have sapped the strength of armies. More soldiers in the world's history have succumbed to bacteria than to bullets. Until recently, the high morbidity and mortality rates among troops have been notorious. It is only in recent years that the results of sanitary science have been able to safeguard the soldier and sailor against many infections that formerly decimated the ranks.<sup>1</sup> In fact, the fruits of preventive medicine are most conspicuous, picturesque and convincing in armies and navies. Formerly the medical service dealt principally with the surgery of wounds and the treatment of fevers; now, however, the larger part of the energy and skill of the medical corps is directed toward their prevention. Therefore, the medical officer must be a sanitarian as well as a physician and surgeon.

The first successful use of preventive measures dates from the efforts of Florence Nightingale in the Crimean Campaign (1854), and on a larger scale to the methods employed by the Germans in the Franco-Prussian War of 1870-1871.

The subject of camp sanitation, however, is not new. Thus we read in Deuteronomy, "Thou shalt have a place also without the camp, whither thou shalt go forth abroad: And thou shalt have a paddle upon thy weapon: and it shall be, when thou wilt ease thyself abroad, thou shalt dig therewith, and shalt turn back and cover that which cometh from thee." If the above primitive injunction had been followed by

<sup>1</sup> The conditions during our Civil War are thus described by Charles Francis Adams:

"The trouble, however, was that we were all so inexperienced, and knew nothing of the laws of health and self-preservation, and we thought those laws not worth knowing. Why any of us survived I cannot now see, but we were young and robust as a rule, we lived in the open air and we were at least temperate. On the other hand, we had no schools of instruction. . . . We were, too, encamped in low lands for convenience of access to water on account of the horses. . . . With a suggestively growing sick list, it never occurred to me to change my camp to higher ground or drier soil, to put my men in motion on some pretext, or to alter my own diet. I stupidly blundered along, myself sickening day by day. . . . These simple precautions never seemed to suggest themselves to our army medical men." "Autobiography of Charles Francis Adams," pp. 146, 162, and 163.

our troops in the Spanish-American War it would have saved thousands of cases of sickness and death from typhoid fever.<sup>2</sup>

Soldiers are notoriously improvident, indifferent and uninformed concerning questions of health. Constant and skilled supervision is necessary over food, water, clothing, ammunition, personal hygiene and safety. Hence instruction in the essentials of military hygiene and first aid becomes one of the prime duties of the medical corps.

Military hygiene is only a special application of the facts and principles of general hygiene, applied to the particular conditions of camp, barrack, field and march. The efficient medical officer must be acquainted with these particular conditions, else incompetency is bound to result. Training of the medical officer for military service is therefore an important part of preparedness.

In campaigns the objects of medical administration are first and foremost the preservation of the strength of the army in the field, and secondarily the care and treatment of the sick and injured at the front, in the line of communications and in the home territory. The first object is obtained by an application of all sanitary measures; by the retention of effectives at the front and the movement of non-effectives to the rear without obstructing military operations; and finally by the prompt succor of wounded on the battlefield and their removal to the rear, thus preventing the unnecessary withdrawal of combatants from the firing line to accompany the wounded, and promoting the general morale of the troops.

The diseases of the civil population are reflected in the soldier and sailor. It is therefore impossible to obtain a satisfactory health record in large bodies of troops, if the public health of the civil population receives imperfect attention. A nation at war naturally focuses its attention upon the health of the military forces, but it cannot afford to ignore the civil population. It should always be remembered that only about 10 per cent. of the population is available for active service in the field, leaving 90 per cent. of the entire population to be cared for at home. In previous wars, and to a certain extent in the World War, this phase of the question was not given the consideration it deserves.

Sanitary isolation between the military forces and the civil population is neither possible nor desirable. If measles, tuberculosis, plague, syphilis, gonorrhea, or other infections prevail among the civil population, these same infections will soon find their way into the troops. The commerce is reciprocal, for the troops return the infection into the homes.

The diseases of the World War differed somewhat from those of previous wars, for the reason that never before in the history of the world

<sup>2</sup>One-third of our entire command had typhoid fever. There were about 20,000 cases and 3,000 deaths in a total of about 107,000 officers and enlisted men.

have armies of such vast size been mobilized, and the conditions of actual warfare have changed, so as to strain the most robust constitution. Prolonged trench warfare depresses vitality in a way unknown to campaigning in the open. This favored the development of tuberculosis; and the necessity for frequent leaves of absence fostered the spread of venereal diseases.

Several "new" diseases, such as "trench fever" and "war nephritis," were described. The conditions of trench fighting have brought out many cases of "trench foot," a serious and disabling condition. Weil's disease, influenza, pneumonia, measles, and other infections were prevalent.

Against this record, we have triumphs of sanitary science in controlling typhoid fever, cholera, dysentery, and other diarrheal diseases, and satisfactory control of typhus, plague, smallpox, and other serious insect-borne infections.

**Comparative Loss in Campaign from Sickness and Wounds.**—From the records of past campaigns many valuable lessons may be drawn. In 1809, during the Walcheren expedition the mortality in the British army from disease was 346.9 per 1,000 effectives, while only 16.7 per 1,000 were killed by the enemy. In the Russian campaign against Turkey, in 1828, it was estimated that 80,000 men died of disease and 20,000 in consequence of wounds. During General Scott's campaign in Mexico the losses from disease alone exceeded 33 per cent. of the effective strength of the forces under his command; and of a single regiment of Indiana volunteers, which entered the service 1,000 strong, only 400 returned to the State for muster out. Laveran states that in the Crimean War the allies lost 52,000 men in six months, of which number 50,000 men were unharmed by the Russians. During the entire war, according to Viry, the French lost no less than 95,000, of whom 75,000 died of disease.

The mortality among the United States forces in the Civil War was divided as follows:

Mortality	White	Colored	Total
Killed in battle .....	42,724	1,514	44,238
Died of wounds .....	47,914	1,817	49,731
Died of disease .....	157,004	29,212	186,216
Died, cause unknown .....	23,347	837	24,184
Total .....	270,989	33,380	304,369

From the most reliable data available, the deaths in the armies of the Confederate States during this struggle did not fall short of 200,000, three-fourths of which number were due to disease and one-fourth to the casualties of battle.

In the War of 1866 against Austria, out of a total strength of

437,260, the Prussians lost in an unusually brief and decisive campaign 6,247 men by sickness and 4,450 at the hands of the enemy. The Franco-Prussian War of 1870-1871 furnishes the only exception to the general rule that more men are killed by disease than by the weapons of the enemy, since of the German army 33.7 per 1,000 strength fell in battle, while only 18.6 per 1,000 died of disease. This result was largely due to the observance of sanitary precautions, assisted, no doubt, by the brevity of the campaign, the rapidity of the movements and the fact that active operations were conducted during the most healthful season of the year. In the Russo-Turkish War of 1878, according to Viry, the Russians lost 102,799 men, of whom only 16,578 were killed by the enemy. During the Spanish-American War of 1898, for the five months which included the total period of hostilities, of the 274,717 officers and men enrolled in the United States forces there were only 345 men killed by the enemy, while about 3,000 died of typhoid fever. It is said that of the old soldiers carried on the United States pension rolls, those disabled by disease are more than four times greater in number than those pensioned for wounds.

In the World War, for the first time in history, we lost fewer men from disease than from wounds.

Killed in action .....	33,123
Lost at sea .....	733
Died of wounds .....	13,555
Died of accident .....	4,887
Died of disease .....	23,375
Total .....	<hr/> 75,673

## RECRUITS AND RECRUITING

Nothing is more mistaken than the lay idea that any man with courage would make a good soldier. A suitable recruit must not only be able-bodied, but he must have good character, mentality, habits, and temperament. A minor physical defect may, under the strain and privations of a campaign, not only incapacitate him, but require the attention of several useful soldiers in taking care of him. Nor does the story end here, for later he may secure a pension from a government which he never usefully served. This is too commonly the case with volunteer troops whose standards of recruiting are below that of regular troops.

In 1900 the admissions for disease in the United States Army per 1,000 strength were 1,821 regulars, against 2,762 volunteers; while the mortality was 12 and 25, respectively.<sup>3</sup>

<sup>3</sup> "Military Hygiene," by Valery Havard, 2d ed., p. 172. Wm. Wood & Co., 1914.

During the war with Mexico the regular troops, who bore the brunt of the campaign, lost about two-thirds as many from disease and by discharge for disability as did the volunteer troops, the former having been physically examined, whereas the latter had not. In the Civil War the annual mortality from disease was 32 per 1,000 in the case of the regular army, and 55 per 1,000 from the less carefully examined volunteers. At the same time the annual loss by discharge on certificate of disability was 68 per 1,000 for the regulars and 91 per 1,000 for the volunteers.

During the World War there were examined physically at local boards about 2,510,000 men between the ages of 21 and 30 years. Of these 46.8 per cent. were found to have defects and 730,000, or 29.1 per cent., were rejected on physical grounds. Additional physical defects discovered or emphasized in mobilization camps, resulting in the discharge of the men, would perhaps increase this to nearly 35 per cent.—a rejection of more than one man out of every three.

The effectiveness of a force depends upon its vigor rather than upon its size. The strength and health of a military organization is based upon the physical character of the individuals composing it, and celerity of movement and the ability to bear hardship are imperatively demanded in the successful manipulation of armies. Recruits must be of trustworthy physique and sound constitution before military character can be developed, and the physically, mentally, and morally defective are hence to be uniformly rejected as unfit for service. The Medical Corps has, therefore, an important responsibility in examining recruits for enlistment in the various services; not alone the health of the army, but military efficiency depends upon the care with which candidates are selected and assigned. The recruiting depot further acts as a quarantine to keep communicable diseases out of the army.

The recruit is surrounded by temptations—especially alcohol and prostitution—and a policy of timely restraint, education, and prophylaxis in connection with mobilization is imperative. The recruit is suddenly removed from the restraining and supporting influence of the home and home society. He is in the adolescent years when desire is strong and the will weak.

It is an interesting but readily understandable fact that, whereas voluntary applicants for enlistment endeavor to conceal defects, conscripts try to escape service by magnifying existing defects or feigning nonexistent ones. In the examination of conscripts, therefore, a skeptical attitude of mind should be maintained toward alleged disabilities.

It must also be kept in mind that there are numerous corps and departments in the various armies of the service. The requirements for recruits in each of these differ somewhat. Thus, the requirements of height and weight are different for infantry, cavalry, and artillery;

vision is especially important in the signal corps; the requirements for the medical corps, the paymaster's corps, the commissary corps, the ordnance department, the engineering corps, the aviation service, etc., vary, and each has its own special qualifications. Especially in examining for an officer's commission, it is important that the medical examiner be acquainted with the particular service in which the candidate intends to enlist.

City bred men make better soldiers for immediate service than country lads; however, the latter outstrip the former after a year or two of training. Town bred men are quicker to understand what is required and hence are sooner trained. They are usually immune to measles, whooping-cough, mumps, and other diseases of childhood, which often prevail in recruiting camps, and are apt to lower the standard of health and vigor of country youths. Recruits from cities are more likely to be familiar with some technical trade which is of value in war.

### *THE PHYSICAL EXAMINATION*

When a recruit arrives at a recruit depot he immediately receives his physical examination. This is completed by medical officers detailed for the purpose, and is particularly thorough. Under the volunteer system of recruiting, pressure is at times brought to bear on the examining surgeon to accept men who are subnormal. This pressure may be from the man personally, or from some one else who is interested in him. This naturally adds to the difficulties of the situation, but it is always the wisest course for the examining surgeon to reject all those candidates who do not come up to the standard provided in the recruiting regulations.

Rules for the examination of recruits are issued in pamphlet form from the War Department under the title of Special Regulations 65, Nov. 8, 1918, and they set forth the defects which call for the rejection of candidates. These are all pathologic defects, and these specifications should be carefully followed by all officers performing this work.

An applicant for first enlistment to the Regular Army must be a citizen of the United States, between the ages of 18 and 35 years, of good character, temperate habits, able-bodied, free from disease, and must be able to speak, read and write the English language. For the Conscript Army authorized by Congress the age limits were 21 to 30.

**Age.**—It is generally recognized that youths under 22 cannot stand the strain and privations of war. Up to the twenty-fifth year growth and development are taking place, the bones are not fully formed, nor have they reached their final hardness; the epiphyses have not become incorporated with the shafts of the long bones; the joints are not fully developed; the chest has by no means attained its full capacity; the

organs of the body in general are immature. The heart is unduly susceptible to overstrain, and the muscles lack endurance. Napoleon said that "boys only serve to fill the hospitals and encumber the roadside." Further, young men are more susceptible to many infections, both on account of youth and because they are more careless, reckless and inexperienced. On the other hand, young men are quick to learn, ready to act, brave, and amenable to discipline. Under eighteen years of age the candidate for enlistment must have the consent of parent or guardian.

The so-called "veterans" of Napoleon were men of 26 to 28 years, and his "old guard" consisted of men from 28 to 29; at Austerlitz the oldest soldiers were 33 and at Friedland 36 years old (Rouget et Dopter). It will seldom be in the interest of the service to enlist men over 30 years old, and the legal limit of 35 is only intended to be used in times of emergency. After 20 years in the ranks, and when past 40 years of age, the soldier soon becomes unequal to the arduous duties of field service. During the World War the age limits were stretched to the utmost by all the nations actively engaged.

Strong, well developed boys, with a burning desire to enter the service, but under the legal years, sometimes try to deceive the recruiting officer as to their correct age. According to Greenleaf, there are certain evidences of maturity which usually accompany the period of legal majority, and with which the recruiting officer should familiarize himself. "At 21 years of age, the wisdom teeth are usually cut, and on each side of both jaws there should be found five grinders, viz., three large double or molar teeth, and two smaller double or bicuspid teeth. In case of the loss of teeth, the spaces originally occupied by them may be seen." Further, the color of the scrotum, and the development of hair under the axillae and about the genitals help to determine correct age.

**Character and Mental Condition.**—These are determined by the recruiting officer so far as possible by demeanor, expression, manner of answering questions, absence of obscene tattooing, nature of glance, etc. It is exceedingly difficult in a brief examination to appraise character. It is also difficult, but very important, to discover degeneracy or mental unfitness. The medical examiner must be familiar with psychiatry. Mental unfitness is often more disqualifying than physical defects.<sup>1</sup> Dementia precox is the most important mental disease from the standpoint of military service—feeble-mindedness in itself is not so serious a factor. Syphilis and heredity are the underlying causes of most mental diseases. Every effort should be made to detect psychoneuroses, epileptics, alcoholics, and drug addicts.

<sup>1</sup>"Exclusion of the Mentally Unfit from Military Service." Sheehan. *U. S. Naval Med. Bull.*, vol. X, No. 2, April, 1916, p. 213.

In the United States Army during the year 1913 the discharge rate for mental disease was higher than that from any other cause.

**Height, weight and chest measurements** are recorded. They should conform to established standards and bear certain definite proportions one to another.

TABLE OF PHYSICAL PROPORTION FOR HEIGHT, WEIGHT, AND CHEST MEASUREMENT  
ACCEPTED STANDARD MEASUREMENTS

Height		Weight, Pounds	Chest Measurement	
Feet	Inches		At Expiration : Inches	Mobility : Inches
5 1/12	61	120	31	2
5 2/12	62	120	31	2
5 3/12	63	124	31	2
5 4/12	64	128	32	2
5 5/12	65	130	32	2
5 6/12	66	132	32 1/2	2
5 7/12	67	134	33	2
5 8/12	68	141	33 1/4	2 1/2
5 9/12	69	148	33 1/2	2 1/2
5 10/12	70	155	34	2 1/2
5 11/12	71	162	34 1/2	2 1/2
6	72	169	34 3/4	3
6 1/12	73	176	35 1/4	3
6 2/12	74	183	36 1/4	3
6 3/12	75	190	36 3/4	3 1/4
6 4/12	76	197	37 1/4	3 1/2
6 5/12	77	204	37 1/2	3 3/4
6 6/12	78	211	38 1/4	4

Variations from this standard are permitted if the applicant is active, has firm muscles and is evidently vigorous and healthy.

The requirements of the War Department (Circular No. 1, August 5, 1913) specify the minimum height for infantry, coast artillery and engineers at 64 inches; for cavalry and field artillery between 64 and 72 inches; for mountain batteries between 68 and 72 inches. Foreign countries have a minimum standard of less than 62 inches, save Germany, 62, and England, 64 inches.

The minimum weight for all branches of our service is 128 pounds, as stated in the "Rules for Examining Recruits," General Orders, No. 66, War Department, 1910, Circular No. 1, 1915. An otherwise desirable candidate as light as 120 pounds may be accepted. But no candidate who weighs less than 120 pounds will be accepted without special authority from the Adjutant General of the Army. The maximum for infantry, coast artillery and engineers is 190 pounds; for cavalry and field artillery, 165 pounds.

Chest measurements are obtained at the end of forced inspiration and forced expiration. The chest girth is taken by means of a tape measure passed around on a line including the lower portions of the scapulae, and

on a level with, or just below, the nipple. Chest measurements do not give as good an idea of the respiratory capacity as the spirometer, the use of which has not yet become general in recruiting offices. The rule in the United States Service is to reject men who measure less than 32 inches about the chest, unless specially qualified and desirable. For men under 67 inches in height the difference between inspiration and expiration should be not less than 2 inches; between 67 and 72 inches, not less than 2.5 inches; 72 inches and above, not less than 3 inches. The chest capacity or "mobility," well called "vital capacity," is one of the best indexes of vigor and endurance.

As a general rule, the higher the social class to which the recruit belongs, the better he will be physically as well as mentally, for it is notorious that in European armies, where military service is obligatory, the officers are usually taller and heavier than the enlisted men. Vision is an exception to this rule, for it grows more imperfect as we ascend the social scale, so that perfect eyesight is oftener found in the middle and lower than in the higher and better educated classes.

**Vision.**—Good vision is of greater importance for the soldier than formerly, because of the conditions of modern warfare: the distant and hidden enemy, often with only the head showing if anything, and the inconspicuous color of the uniform, blending with the background. Binocular vision is important in estimating distance. A higher degree of impairment of vision is more permissible in the left eye than the right—the eye used in shooting. It has been found that a visual acuity of 20/40, or even 20/70, in the aiming eye is consistent with good shooting, provided the soldier is able accurately to focus both sights of the rifle. The prescribed visual requirements in the United States Army are as follows:

1. For the line of the Army: 20/40 for the better eye, and 20/100 for the poorer eye, provided no organic disease exists in either eye.

Recruits may be accepted for the line of the Army when unable with the better eye correctly to read all of the letters on the 20/40 line, provided they are able to read some of the letters on the 20/30 line.

2. For the Ordnance Department and for the Medical Department: 20/70 in each eye, correctible to 20/40 with glasses, provided no organic disease exists in either eye.

Candidates for a commission, and candidates for the United States Military Academy, must have vision that does not fall below 20/40 in either eye, and not below 20/20 unless the defect is a simple refraction error, not hyperopia, is not due to ocular disease, and is entirely corrected by proper glasses. Hyperopia requiring any spherical correction, anisometropia, squint, or muscular insufficiency, if marked, are causes for rejection.

Color sense is tested with the usual skeins. Color blindness is a cause for rejection in the signal corps and the air service,—also to the United States Military Academy, and for commissioned officers. By color blindness is meant red, green, or violet blindness, and not confusion of the delicate shades of blues, greens and purples.

To test for color blindness, the colored skeins should be mixed in a pile, and test colors (primary red, green, etc.) placed apart and the applicant told to select all the skeins that resemble the test colors. The names of the colors should not be used in making the test. Each eye is tested separately. See page 923.

**Teeth.**—The teeth must be serviceable and should be reasonably free from periodental trouble which may lead to secondary and serious infections. The actual number of teeth is less important than good occlusion. Unless four pairs of teeth oppose, it is a cause for rejection. It must be remembered that the field service ration is apt to be not well cooked. False teeth may be lost or broken. Caries should be corrected before enlistment, for the Army dental surgeons are overworked.

**Vaccination.**—All recruits are vaccinated against smallpox and are required to take the typhoid prophylactic inoculations. A record is made of this work, so that it is always known at what time such vaccinations have been given.

Under special circumstances prophylactic vaccines against cholera, plague, paratyphoid, dysentery and other infections are used. Polyvalent vaccines may be used—that is, three, four, or more bacterial vaccines may be mixed and injected at the same time. Thus in the Serbian campaign a tetravaccine was used consisting of typhoid, paratyphoid A and B and cholera.

**General.**—The recruiting officer takes into account the cleanliness of person and clothing. The examination should be made stripped. The applicant is observed while walking, running, and jumping. Special examinations are made of the lungs, heart, teeth, skin, joints, and feet; for the presence of hernia, varicocele, and other disqualifications. Particular attention is paid to the condition of the legs, ankles and feet. Varicose veins, large or recent bunions, corns on the sole, flat foot, and “hammer toe” disqualify the applicant for marching and are causes for rejection.

When accepted, recruits receive preliminary training in tactics and barrack life. A soldiers' handbook is issued to them in which are discussed the articles of war, guard duty, rations, clothing, arms and equipment, codes for signaling and an outline of first aid and care of health.

*TRAINING*

Training consists partly of drills and physical exercises, given primarily to develop the soldier, and discipline and instruction in military organization and tactics. The medical officer gives instructions in personal hygiene, including talks on venereal diseases, the latter being considered from both the moral and the physical standpoints.

As soon as his training has progressed sufficiently to justify his assignment to a permanent company, the recruit is sent to some regiment. There his military training progresses in the company of his fellows, and after six or twelve months' service he is classed as a trained soldier.

The object sought in physical training for military purposes is not strength, but rather agility, endurance, and coördination. In addition to marching and setting-up drills, boxing, fencing, wrestling, skating, swimming and games are useful. Exhaustion or overstraining must be avoided. It is a mistake to try to make the soldier too quickly. Many cannot stand the pace.

Marching should be the principal outdoor exercise of the soldier. It is also the most exhausting, owing to the weight of equipment carried. Good marching is obtained only by careful preparation, strict discipline, and regard for sanitation. Marches, at first short, are gradually lengthened until the soldier can cover 15 or 20 miles a day bearing his full equipment without marked fatigue and with feet in good condition.

Napoleon is credited with the remark that battles are won with legs rather than with arms. Success in war depends largely upon getting there first with the most men. Transportation by motor trucks and other modern means has not diminished the importance of marching.

Young soldiers and young recruits unaccustomed to active muscular exercise soon tire out. The exercises, therefore, should be simple at first with gradually increasing severity. All nations realize that on the soldier's endurance may depend success or failure; therefore, soldiers of all countries are given systematic exercise in garrison and encouraged in athletics so far as possible. Manuals are issued for both gymnasium and outdoor work. For our soldiers, advantage is usually taken of the material at hand, and the exercises favored are: 1. Setting-up exercises, largely limb and body movements. 2. Marching, double time and running. 3. Rifle and saber exercises. 4. Climbing, jumping and vaulting. 5. Gymnastic contests. 6. Athletic contests, wrestling and boxing. 7. Swimming.

The beneficial effects of these exercises soon manifest themselves in stronger muscles and increased endurance.

In military training there is usually an initial loss in weight, but owing to the healthful régime, good food, and regular habits, the recruit soon puts on weight.

Training should include personal hygiene and the recruit should be required to follow certain general rules:

The body must be kept clean and free of vermin; a daily bath not only cleanses but refreshes the body.

The hair of the head should be trimmed close.

The tooth brush should be used daily or oftener.

The hands should be washed before eating and after leaving the sink.

The feet of dismounted soldiers should be cleaned daily on arrival in camp and clean socks put on to replace the ones used on the march.

The soldier should not drink or eat food prepared or sold from an unauthorized source.

**Duties.**—The duties of the medical officer are varied and often exacting. They include both preventive and curative medicine. In general, the duties are: to look after the health of troops in camp, barracks, and on the march; attend to the wounded on the battlefield; organize and administer hospitals, ambulance and transport service, quarantine stations, medical supply depots and laboratories; to inspect and supervise the quality of the food and water; to instruct officers and men in military hygiene and first aid; to examine recruits; and to assist both staff and line in all questions involving medicine, surgery, hygiene or sanitation.

An Army Medical School is maintained at Washington for the purpose of instructing the officers of the Medical Corps, and in turn the members of the Medical Corps give general instruction in military hygiene, first aid, etc., to officers and men of the staff and line.

The duties of the medical officer are specified in regulations which should be carefully studied and followed. The regulations in the Manual for the Medical Department are only part of the general body of regulations with which the medical officer must acquaint himself. Obedience, uniformity, and discipline are essential qualities for military efficiency.

The medical officer of the army is not only a physician, but also a soldier, and as such must be a component part of a disciplined machine. Whether in the field, on the march, or in camp, he has his position and must fit into it, or there will be friction. All medical officers are mounted, and it is therefore important to know how to ride a horse and manage it in maneuvers. Again, emergencies arise when it is necessary for the medical officer to become an active combatant. He must know the routine of getting supplies, the position of the sanitary personnel on the field in time of war, the disposition of the property of the wounded, and the method of reporting various activities. Therefore, it is important for the medical officer to spend two to four months in a training camp. It is also important that he be familiar with military law.

Military law is provided for the government of armies in peace and war. There are two divisions of military law: One is called international law and treats particularly of the action of armies and individuals of those armies in time of war, or at any time when they come in contact with foreign nations. That part of international law which is of interest to our armies in time of war is laid down in a small book published by the War Department called "The Rules of Land Warfare," and can be obtained by application to the Adjutant General, Washington, D. C. These rules are of decided interest to the medical officer, for his actions when captured by the enemy, or in other contingencies, are laid down carefully and must be obeyed to the letter.

The other division of military law is for the internal government of the army and is covered by the "Articles of War," which form the common law for the army. Offenses are classified and punishments provided in the same way that the civil law is written.

The educational duties of the Medical Department are of a twofold nature, to the public, and to the military service. The Surgeon General's Library at Washington is "the great, central medical library of reference of the Nation." The Medical Department also maintains the Army Medical Museum and an Army Medical School in Washington, at which regular courses of instruction are given to medical officers; and the Medical Department Field Service School at Carlisle, Pennsylvania; the Medical Research Laboratory and School for Flight Surgeons at Mineola, Long Island, for training medical officers in the examination and care of the personnel of the air service.

The objects of medical administration in campaign are: "First, preservation of the strength of the army in the field—(a) by the necessary sanitary measures; (b) by the retention of effectives at the front and the movements of non-effectives to the rear without obstructing military operations; and (c) by the prompt succor of wounded on the battlefield and their removal to the rear, thus preventing the unnecessary withdrawal of combatants from the firing line to accompany the wounded, and promoting the general morale of the troops.

"Second, the care and treatment of sick and injured at the front, in the line of communications, and in the home territory."<sup>5</sup>

## EQUIPMENT

The soldier's equipment includes his arms and accouterments, clothing, and all other things necessary for his comfort and health. All articles of equipment must be of good quality, of greatest strength and best wearing power, with the least possible weight. There then remains

<sup>5</sup> *Manual of the Medical Department.*

the very important problem of distribution on his person so as to be carried with the minimum muscular exertion and fatigue. In all armies this problem is given much attention.

German experiments applied to the respiratory capacity of soldiers have shown that their loads, including overcoats, should seldom exceed 55 pounds. The weight of the equipment of various nations is as follows:

United States of America, new equipment.....	48 pounds
“ “ “ “ old “ .....	56 “
Italy .....	58 “
France .....	57 “
England .....	52 “
Germany .....	59 “
Austria .....	61 “
Russia .....	60 “
Japan .....	55 “

The above weights are approximate, varying according as the overcoats, trenching tools, shelter tents, etc., may be temporarily discarded. It is important that the weight be divided so that unnecessary articles can readily be detached before going into battle, or where transportation

FIG. 180.—PROPER AND IMPROPER METHODS OF DISTRIBUTING THE EQUIPMENT.  
(Havard's "Military Hygiene," Wm. Wood & Co.)

is available. The haversack has been discarded in our army and its place taken by a pack arrangement, wherein weight is distributed over the soldier's back with the least disturbance to center of gravity, thereby saving extra muscular exertion.

The weight of the United States equipment is divided as follows:

TABLE OF ARTICLES OF EQUIPMENT, WITH WEIGHT OF EACH (Keefer)

	Pounds	Ounces
Clothing (with extra pair socks).....	7	13
Rifle and sling.....	9	.92
100 cartridges.....	5	15.88
Cartridge belt.....	1	6.1
Trenching tool.....	2	2.04
Bayonet and scabbard.....	1	5.48
First aid pack and ponch.....	..	5.59
Canteen filled with cup and cover.....	3	10.03
Haversack.....	1	9.85
Pack carrier.....	..	7.32
Blanket.....	3	1
Shelter tent half with 5 pins.....	2	11.68
Poncho.....	3	....
Meat can, knife, fork and spoon.....	1	1.21
Rations (2 reserve) with containers, 1 bacon can, 1 condiment can.....	4	1.72
Toilet articles: towel, soap, comb, tooth brush.....	..	7.
	48	2.83

This equipment is so divided that shelter halves, etc., can be discarded before going into battle, thus reducing the total weight, which, with two extra bandoleers of cartridges, brings the weight to 39 pounds.

In wagon trains, there are carried for each man an undershirt, a pair of drawers, two pairs of woolen socks, a pair of shoes with extra laces, sweater and mosquito bar.

**The First-aid Packet.**—The first-aid packet has done much to reduce mortality from wound infections. When a ball enters or goes through the muscles or soft parts of the body alone, generally nothing need be done except to protect the wound or wounds with the contents of the first-aid packet.

Each packet contains:

(1) Two bandages of absorbent sublimated (1:1000) gauze, 4 by 84 inches.

(2) Two compresses of absorbent sublimated (1:1000) gauze, each composed of  $\frac{1}{2}$  square yard of gauze, folded so as to make a compress  $3\frac{1}{2}$  by 7 inches.

(3) Two No. 3 safety pins wrapped in waxed paper.

The packet thus prepared is placed in an hermetically sealed metal case with a suitable arrangement for easy opening. All contents of the case must be sterile. Dimensions of the case should not exceed 4 by  $2\frac{1}{4}$  by 16 inches.

The shell-wound dressing consists of:

(1) One compress composed of 1 square yard of absorbent sublimated (1:1000) gauze, so folded as to make a pad 6 by 9 inches.

(2) One bandage, 3 inches wide by 5 yards long, of absorbent sublimated (1:1000) gauze, loosely rolled and wrapped in parchment or waxed paper.

(3) Two No. 3 safety pins wrapped in waxed paper.

The whole dressing is wrapped in tough paper, with directions for application printed thereon.<sup>6</sup>

**Clothing.**—The things sought for in the soldiers' clothing are uniformity and neatness in appearance, maintenance of body temperature, and protection from wet and traumatism. It must allow full freedom of muscular action, avoid constriction of any vital part of the body, and must not interfere with physiological function. The chief function of clothing is to assist in the maintenance of an equable body temperature. Further, there are military reasons for the adoption of the fabric, color and style of clothes. Wearing quality and protection not only against the elements but the enemy must be considered. In modern warfare showy uniforms, such as worn by the British "red-coats" and the French red-trousered Zouaves, have given way to colors which make less conspicuous targets. The colors now preferred are brown, olive-drab, olive-green, green-gray, and similar shades that blend with the landscape. It is also now customary to have little difference between the uniforms of officers and men. The great loss of officers in the British Army in the early part of the World War was due partly to their distinctive dress and conspicuous station in front of the command.

Uniforms made of a heavy, feltlike material will absorb rain and perspiration, gather dirt, and when driven into the body in shell wounds are very apt to give rise to serious infections.

Allowances are usually made for the dress of native troops. For instance, the Cossacks habitually wear their sheepskin coats; the Philippine Constabulary have a distinctive uniform; the Sikhs wear their turbans, etc. Other reasons such as climate and occupation govern the type of uniforms. For instance, our troops in Arctic posts are supplied with mackinaws, fur caps and gloves; aviators affect a tight-fitting, closely woven uniform, with cap and mask designed to offer but little resistance to the wind and to prevent the radiation of body heat.

The materials used for clothing for military purposes are: wool, cotton, linen, paper, leather, fur, rubber, etc.; also such mixtures as shoddy, merino, etc.

Of these substances, *wool* is perhaps the most valuable. It is a poor conductor of heat, absorbs water, but gives it up slowly; whereas, cotton becomes wet, dries quickly, and therefore feels damp and chilly when moist. Wool, however, has the disadvantage of shrinking on washing. *Cotton*, besides being cheap, wears well, is cool, and does not shrink.

<sup>6</sup>Drill Regulations and Service Manual for Sanitary Troops, U. S. A., 1914, p. 143.

Merino, a mixture of cotton and wool, is much used for underwear. *Linen* conducts heat more readily than cotton, but absorbs moisture poorly; furthermore, it is more expensive than cotton. Paper conserves warmth and was used by the Japanese for this purpose. A *paper* vest makes an excellent protection against cold winds, and a newspaper between blankets on a cold night helps to keep the body snug and warm and takes the place of extra covering. The usefulness of clothing depends not alone on the material, but on the weave, texture and color of the fabric. White is the coolest and black the warmest, with blue a close second. Olive-drab is somewhat warmer than khaki, which is a closely woven, hard finished, cotton cloth.

*Waterproofing* may be accomplished either by coating the cloth with an impervious substance, as rubber, or by impregnating the fibers themselves. The former is completely impervious, the latter partially. The fibers may be waterproofed by spraying the cloth with a solution of varnish or similar substance; it may be done in the field by means of an aluminium acetate solution. Woolen fabrics may be treated with lanolin dissolved in benzene, thus replacing the fat which made it waterproof for its original owner. Waterproofed fibers are intended to protect against inclement weather, not against cold, for obviously they are pervious to body heat and partially to moisture. On the other hand, rubber and fur retain both moisture and heat. The new infantry *poncho* is of waterproof olive-drab cotton, substituted for the former heavier one of rubber surfaced cloth. *Slickers* for mounted troops are merely longer ponchos designed to cover the saddle and equipment.

*Leather* is largely confined for military purposes to trappings, belts, shoes, coats, etc. For men who handle heavy guns, however, leather gloves are furnished. *Fur* is used almost exclusively for mittens and caps, both of which may be wool lined and are designed solely for service at cold posts.

The total weight of a soldier's uniform varies from six and one-half to twelve pounds, depending upon the climate. The styles, colors, weights, and other qualities of soldiers' clothes are changing continually.

*Headgear*.—An ideal headdress should be light in weight and color, well ventilated, flexible enough to take the shape of the head, and designed to protect both the neck and head from sun and cold; further, it should shield the eyes, be comfortable, and not readily dislodged. Our new service hat, the "Montana Peak," is perhaps the best adapted of all in use, although it has certain disadvantages. The pith helmet has been found by actual experience as well as experiment to be better adapted than any other style of headdress for tropical use. For cold posts fur and canvas caps with ear flaps are issued to our troops. Pressed steel helmets were supplied the troops engaged in trench fighting in the late war. These are designed to protect the head against shrapnel and grenade

fragments. Masks designed to hold chemicals to protect against the so-called "gas curtains" were used abroad, in order to neutralize chlorin and bromin fumes.

*Coats.*—Coats are designed to fit fairly snugly. The service coat should have five inches excess across the chest. The roll collar and lapel are preferable to the standing collar, for the hard, rough use of actual warfare. The former leaning toward bizarre designs and colors, is giving way to the practical ideas of service, utility and warmth. Overcoats no longer have a hood; mackinaws are furnished for service in Alaskan posts. Ponchos are issued to foot soldiers, the idea being borrowed from Central America, where they are much in use. Slickers are regularly issued to mounted troops.

*Leggings.*—Leggings, or articles serving their purpose, are of many kinds and designs. Some armies, as the German, are supplied with high-topped boots, which serve both as shoes and leggings. Leggings or gaiters may be of leather, duck or woolen strips, arranged so as to protect the entire shin or only the lower part. The United States Army legging consists of heavy canvas with reinforced straight edges with a lacing on the side and a stirrup strap under the instep. Putties are used, but have obvious disadvantages.

*Gloves.*—Gloves are designed and issued in many materials and styles. Mention has been made of leather ones provided handlers of big guns. Leather gauntlets are also issued to the cavalry. Fur mittens, wool lined, are provided for northern posts.

*Underwear.*—From the standpoint of hygiene, perhaps the most important part of the fighting man's dress is the underwear. It is supplied our troops in merino, light and heavy wool. An apronlike woolen abdominal protector is recommended for those in whom exposure to cold causes diarrheal disturbances, but its use has not been regarded favorably by our troops. Underdrawers are furnished full length to protect the lower legs against dirt. Socks issued to United States troops are made of cotton, half-cotton, and wool, the light woolen ones being preferred. The English have estimated the life of socks similar to our light wool as being sixty to seventy road miles.

*Shoes.*—While it has long been known that proper footgear is indispensable to an army, it is only within recent years that the subject has been studied scientifically. Disability from poorly fitting shoes is found both in military and civil life, and forms a large percentage of those who fall out during the first few days of maneuvers or the march. Some native troops, as, for example, African native soldiery or our Philippine Constabulary, may wear no shoes at all, while, on the other hand, the clumsy high-topped boots of the Russians and of the Germans as they entered the late conflict were very heavy. Our men probably have better shoes, better shaped and better fitted than those of any other

nation. A board of officers of the United States Army in 1912 made a report on shoes and the soldier's foot, as a result of which the so-called Munson composite last was adopted. The recommendations of the board were: (1) that shoes made over the Board last be adopted; (2) careful fitting, personally by company officers; (3) full series of sizes carried by posts; (4) frequent inspection of feet by commanding and medical officers. These recommendations were adopted with the statement that "hereafter any undue amount of injury and disability from shoes will be regarded as evidence of inefficiency on the part of the officers concerned and as a cause for investigation."

In persons who wear no shoes, the axial line of the big toe, if continued, will pass through the center of the heel (Meyer's line). This fact forms the basis of the Munson last. A foot soldier's pack weighs about 40 pounds, and with this weight his feet tend to flatten and spread in both dimensions. In fitting them, he is required to stand and support a 40-pound weight while

FIG. 181. — THE NORMAL FOOT. Meyer's line.

FIG. 182. — SHAPE OF U. S. MILITARY SHOE. Meyer's line. The dotted line shows slight deviation outward so as to fit the average foot accustomed to shoes.

his foot measure in length and breadth is being taken and recorded. Shoes are then selected from the ninety sizes required to be kept in all posts. The fit should be verified by making sure that there is a free space in front of the toes and sufficient width. It has been found that shoes a trifle loose will cause little inconvenience, whereas those that are tight surely lead to trouble. A figure-of-eight strap passing under the arch above the heel and crossing over the instep tends to prevent chafing of loose shoes for those whose foot peculiarities require them.

A recruit's foot, fitted in the manner outlined above, will so develop as a result of military life that another fitting and size may be necessary some months later, after which the foot ceases to spread.

Munson recommends the following method of breaking shoes in quickly: Have the men stand in water for a few minutes so that the lower parts of the shoes become wet and pliable; next have the men walk on level ground until the shoes dry on their feet. Afterwards, the shoes may be waterproofed by rubbing with neat's-foot oil. The disadvantage of thorough waterproofing is that it prevents ventilation, and the retained warmth and perspiration have a tendency to soften and macerate the skin. Hence, it is usually better to allow the feet to get wet occasionally.

*The Canteen.*—The canteen should be scalded inside and out when new, and from time to time afterwards. The scalding water removes the sizing from the cloth covering of a new canteen, making it more absorbent. To cool the contents, wet the outside covering and hang in the breeze. It is usually best to fill the canteen at night. The men should be taught to conserve the supply and not drink too much water on the march. The man who empties his canteen early in the day is likely to drink from unauthorized sources on the march. The habit of indiscriminate drinking from another man's canteen should be discouraged.

On the march, water is carried in the canteen and in the water keg on the company wagon. A water wagon is furnished as a part of the equipment of the modern army.

### **DISEASES OF THE SOLDIER**

The diseases of the soldier do not differ from those of the civil population, but military conditions favor the spread of many infections. There are but few infections peculiar to camp and field life. Most of the epidemics of camps and barracks are preventable. In former days, soldiers and sailors suffered severely from the results of overcrowding in unsanitary camps and barracks, which favored the spread of all communicable infections, especially those of the respiratory tract, the intestinal tube and the skin.

The most frequent diseases of soldiers and sailors are typhoid, dysentery, diarrheal diseases and other gastro-intestinal infections; pneumonia, tuberculosis, influenza, common colds, sore throat, and other inflammations of the respiratory tract; measles, mumps, cerebrospinal meningitis, scarlet fever, smallpox and other infections. At times the army may suffer from hookworm disease, especially in prison camps in southern zones, where proper disposal of feces is not practiced. Dengue, meningitis, cholera, plague and typhus fever may occur as epidemic outbreaks among the troops. Improper rations may lead to beriberi or scurvy; campaigning in hot weather will result in a number of heat prostrations or even in sunstroke. Soldiers and sailors are also apt to be troubled with lice, fleas and ticks; skin diseases are common and troublesome. Conditions affecting the feet incident to marching are frequent and important (pages 1456 and 1463).

All the preventable diseases above mentioned are fully treated in other portions of this volume, and need therefore not be repeated here, for their prevention is the same with the soldier as with the civilian. In fact, the problem of preventing these infections in a well-organized force under good discipline is simpler than among the civil population.

The diseases that affect the soldier and sailor are simply a reflection of the same diseases that prevail in the civil population. Sanitary isolation to guard the sailor and soldier against infection is, therefore, of prime importance.

The diseases transmitted mainly by contact find favorable conditions for spread in camps, barracks, military prisons, and on board ships. Therefore, one of the first indications in preventing as well as checking an epidemic is to scatter the command in many small sanitary units and over as wide a territory as practicable. Measles, mumps, scarlet fever and other diseases common to childhood are very apt to break out, especially in camps recruited from country districts. When introduced, these diseases spread like wild fire among the susceptible.

Mental and nervous breakdowns often develop, owing to the strain and unusual conditions. This happens in persons who otherwise might go through life without showing signs of mental derangement.

**War Gases.**—The most important members of the group of lethal gases are chlorin, phosgen and chlorpicrin. These substances are alike in that they act on the respiratory tract, producing edema and congestion. Chlorin acts with extreme rapidity. The toxic action of phosgen is slower probably because, to produce its effects, it must undergo chemical change. This fact has earned for phosgen the name of having a delayed action. Chlorpicrin appears to stand somewhere between chlorin and phosgen, both in regard to the type of influence provoked and in the rate of production of intensive edema.

## SANITATION IN CAMP AND ON THE MARCH

### PERSONAL HYGIENE OF THE SOLDIER

**The March.**—Troops marching in close formation suffer from so-called "crowd poisoning"—believed to be due mainly to heat and humidity, aggravated by dust (see page 904). It is now customary in nearly all armies to present as wide a front as possible while on the road; usually two columns march along the sides of the road, leaving a ventilating aisle down the middle. Much of the fatigue and hardships of marching have in recent times been relieved by the use of auto trucks and troop trains.

The "route step" is used on the march—that is, each man uses the step to which he is accustomed, but distance in rank must be preserved. For ordinary marching, the step, according to the United States Regulations, is at the rate of 90 per minute, each 30 inches long, or 2.5 miles per hour. *Quick time* moves at the rate of 120 such steps, or 3.4 miles per hour; *double time* is 180 steps, each 35 inches long, or 6 miles per

hour. The figures for other countries are in general similar to our own. The rate of march is influenced by the character of the roads or ground covered, as well as by head winds, storms, great heat or snow, sizes of command, the burden carried, the discipline, character of the troops, etc.

Marching at night, save for tactical reasons, and marching in the hottest part of the day should be avoided. The command should have a light breakfast before starting. Halts should be arranged by hours rather than by bugle, since the different rates of travel frequently allow the head of the column to finish its rest before the rear has caught up. The head of the column should be taken in turn by the various companies. The first halt usually occurs during the last fifteen minutes of the first hour, to give the men a chance to relieve themselves, readjust clothing, cinches, etc. All other halts during the day are usually about ten minutes for infantry, five minutes for cavalry, and five to ten minutes for artillery, except the noon rest, which should be at least an hour. During halts, the men should be encouraged to lie at full length on the ground, utilizing such shelter as the place affords, and in the case of foot soldiers, to knead the buttocks and thighs to assist in muscular recuperation.

When a "halt order" is given, proper officers of the quartermaster's and medical corps should accompany the officer detailed to go ahead to select a camp site, procure supplies and forage, investigate the water, etc. The medical officer carries his notebook, in which is recorded the choice of camp sites, with a sanitary survey embracing observed data of importance, as well as all other items of medical interest from day to day. Seasoned troops can cover 20 miles day after day, with one day's rest a week. Over 20 miles a day for infantry is regarded as a forced march.

The character of the march is a factor which must be taken into consideration. It must not be imprudently designed, in length or detail, so that the strength and spirits of the soldier will break down; in this case, the more he marches, and the nearer the enemy he gets, the less fit will he be for the encounter. In a hostile country, it is always advisable to keep troops fresh and make only short marches, for fatigue and exhaustion are as inimical to courage and initiative of action as they are to physical endurance. Military restrictions of an unnecessary nature should be avoided as far as possible, since in marching at ease the ordinary journey is relieved of much of its harassing character and becomes a salutary and stimulating exercise. The movements of the individual soldier should not be restrained by precise military rules, but should occur more easily in the better maintenance of equilibrium.

The march should be considered as labor performed in addition to the daily routine of camp or garrison and not at all as the only drain

upon the energies of the soldier. According to Notter and Firth, Cous-tan and others, the average daily work of the ordinary laborer is from 350 to 400 foot-tons, or about  $1/6$  or  $1/7$  the force theoretically obtainable from the food taken by the individual. For a soldier weighing 160 pounds, a march of 10 miles over flat country amounts to 250.30 foot-tons, or what would be a rather small daily expenditure of energy for the civilian laborer. On the other hand, a march of 20 miles with a weight of 60 pounds is alone a very hard day's work for the soldier, without taking into consideration the labor necessarily involved in making and breaking camp, and the other laborious duties incident to the field, and such severe labor could not long be continued without injurious effects. If the weight be badly adjusted or the ground not level, the expenditure of energy becomes greater, as is also the case if it be done in a shorter time. Velocity is also an important factor in determining the strain on heart and lungs. As a matter of fact, however, if very rapid or very long marches are required, the troops are usually sent out in light marching order, with the equipment reduced to the minimum; or they may later bring the labor within their powers of endurance by discarding portions of their equipment en route.

**Forced Marches.**—Forced marches are, fortunately, but rarely required. Anything above 18 or 20 miles is practically a forced march, unless the conditions of the weather, temperature and terrain are extremely favorable. In Mexico, a French column is said to have traveled 30 miles in 5 hours at night, rested 1 hour, and then marched 9 miles further. According to Thomas, the grenadiers of Oudinot, in 1805, pursued the corps of Werneck for three consecutive days, the daily marches being 30, 40 and 50 miles, respectively.

Three regiments of British infantry, in July, 1809, marched 62 miles in 26 consecutive hours, carrying arms, ammunition and packs—in all, a weight of between 50 and 60 pounds. This march implied an expenditure of energy equal to about 600 foot-tons. One of these same regiments, during the Indian mutiny, marched 42 miles in 20 hours, and on the following morning marched 10 miles and engaged the mutineers. But marches of such character may be said practically to exceed the powers of any large military force under normal conditions.

In a forced march, after four hours, the column should be halted for an hour, during which time the men should, if water be at hand, and the weather permit, wash the face, hands, neck and feet; but discrimination as to the duration of the halt must be employed since the men stiffen up if prolonged rests are permitted. A light lunch should preferably be issued at such a halt. Following a forced march a rest of a day will usually be necessary. Hence such a special effort, besides impairing the efficiency of the force, actually gains nothing in distance on a long journey.

One of the most notable instances of long distance marching in a few hours in recent time is that of the City of London Imperial Volunteers who, in South Africa, in August, 1900, covered 30 miles in 10 hours hoping, according to a dispatch of Lord Roberts, to prevent General DeWet from crossing the Krugersdorp-Potchefstroom railway. The celebrated march of Lord Roberts from Kabul to Kandahar, in 1880, over very rough country, was performed in 23 days. The longest day's marches were 20 and 21 miles, and the average distance covered was nearly 17 miles.

Among the best known long marches are several by United States troops, who hold the record for long distance continuous marching from Fort Leavenworth, Kansas, to a point in California, a distance of 1,800 miles, in 190 days, 28 of which were given up to resting, so that in 162 days of actual marching, an average distance of a little more than 11 miles was traversed. In 1860, a portion of another regiment went from Camp Floyd, Utah, to Fort Buchanan, New Mexico, a distance of 1,000 miles, in 140 days.

In the Franco-Prussian War of 1870, a company of French chasseurs marched, in very inclement weather, over an exceedingly difficult road, for 41 hours, with one rest of an hour, another of  $2\frac{1}{2}$  hours, and halts of 8 minutes in each of the marching hours. The exact distance marched is not known, but the instance is cited as one of exceptional endurance and hardship.

**Discipline and Sanitation.**—The two essentials of good marching are discipline and sanitation. Troopers should not be allowed to leave the column without permission. Those who fall out, or desire to, should be examined by a medical officer and a sympathetic watch kept to prevent malingering. Places for latrines at halts are designated where the shallow "straddle trenches" are required to be used, covered with earth and marked on leaving. Water for daily use should be boiled, filtered or treated with "bleach" the night before. In the tropics each man should be supplied two canteens, on account of increased loss through perspiration. Soldiers should be encouraged to drink as little water as possible while on the road. A seasoned soldier conserves the supply in his water bottle. The men should be instructed in the advantages of using a little water as a mouth-wash, followed by a few swallows; also in the use of pebbles and chewing grass to prevent the sensation of thirst. The canteen should be filled only at authorized places, with safe water.

Bathing is very important, especially for foot soldiers. All troops should wash the face, neck and feet as well as the genital and axillary regions with a damp towel and soap, each morning and evening. Daily baths are advisable in permanent camps; tubs and showers can be arranged with pails and makeshifts with very little trouble and are much appreciated by the men.

An army literally marches on its feet as well as "on its belly"; therefore, the care of the feet should be a matter of gravest concern to officers and men. For shoes and their selection see page 1456. Regulations require that foot soldiers bathe the feet daily at the end of the march in cold water, but only long enough to cleanse the skin and set up an invigorating reaction. Clean socks should be donned daily and those removed washed out to dry over night. Extra socks are carried as part of every man's equipment. If possible, the shoes should be changed every few days for the extra pair in the wagon train. If rubbing or creases have been felt, the socks should be turned inside out or changed to the other foot during the halts. If blisters or excoriations occur the serum may be squeezed out and the area protected with adhesive plaster. Abraded areas may be greased. As a rule, practice marches will have been given raw troops to toughen the feet, which may be fortified by a daily soaking in an alum bath or in dilute alcohol. Often, however, foot troubles will arise in experienced troops; when this happens, they should be treated as above outlined. Sometimes the feet are soaped in the morning to lessen friction. A dusting powder composed of talcum 87 per cent., starch 10 per cent., and salicylic acid 3 per cent. is supplied and may be shaken into the socks and shoes. The use of a dusting powder is usually preferred to that of other expedients. In some countries socks, which are not issued to the troops, are substituted wholly by grease, or by bandages, or strips wound around the feet, either greased, dry or dusted with powder. The men should be taught to cut their toe nails across squarely, as this tends to prevent ingrown toe nails and other troubles.

The care of the teeth is important. The soldier should be required to give them daily attention with brush and powder.

While in camp the soldier must look to his own laundry. If a stream is not available the clothes may be boiled in camp. Only within recent years have places for laundering been provided in garrisons. Before 1908, our soldiers were required to have their laundry done outside of the post, or do it themselves—a measure which was anything but satisfactory.

Moving columns bury or burn their excreta and garbage. In camp each company has its own latrines for excreta and garbage, sometimes two of the former, which should be covered and marked on leaving.

The general plan of a camp is shown in Fig. 183. The kitchens are placed as far as possible from the latrines, and the latrines are placed at least 50 yards from the men.

**Sanitary Police.**—Each company commander in turn is "officer of the day," and as such is responsible for camp sanitation. The effectiveness with which policing is done depends largely on discipline. The

officer of the day and his detail look after the proper use of latrines, the proper care of night urine tubs and their lanterns, their proper cleaning and storage during the day, the proper disposal of all refuse, paper, and in general the cleanliness and orderliness of the camp. It is evidence of poor discipline as well as a danger and disgrace when a camp is fringed with fecal deposits and trash. The sanitary inspection should be thorough and complete. The surgeon makes a daily inspection of the camp, usually at 9 A. M., accompanied by the camp sanitary police. Often it becomes advisable to have the entire sanitary police under the control of the chief surgeon in order to abolish nuisances.

Sick call is usually sounded after arriving in camps, and in fixed camps usually at 5 P. M.

In permanent camps, manure produced by the many animals should be disposed of so as not to breed flies or be a nuisance. The picket lines should be thoroughly raked at frequent intervals, and the manure removed daily to a spot several miles from camp. It should then be burned with oil or disposed of to farmers. The picket line should be thoroughly burned over with straw and coal oil to diminish odors and prevent fly breeding.

Field bakeries and eating places should be screened and flies combated with traps, poisons, sticky paper, etc.

The medical officer should be authorized to issue orders in the name of the commanding officer for the immediate remedying of all sanitary defects. He should then be held accountable for results. The mere issuance of orders is not sufficient; success in camp sanitation depends upon enthusiasm, coöperation, and incessant vigilance.

**Transportation.**—Prior to embarking on transports, all troops should be carefully examined to remove those suffering from communicable diseases, and to eliminate any who seem unfit for foreign service. All transports should have an isolation hospital for cases of infection that may break out.

In moving troops by rail, certain sanitary precautions need to be observed. Troop trains travel slowly, because the animals must be unloaded for exercise at intervals, and for the further reason that freight cars are used for baggage. Three enlisted men occupy each double seat or section of a sleeper. This allows the normal accommodation of one person for storage of the equipment of the three soldiers. Inspections of the train must be made at frequent intervals to insure cleanliness, particularly all toilet rooms. A regiment usually travels in three train sections, one for each battalion. The wagons, animals, forage, ration, and baggage of the battalion go with it in the section, so that the troops are ready for independent movement promptly upon entraining. The sanitary personnel is divided among each, and if possible a medical officer should accompany each train.

## CAMP SITES

Sanitary preference, in the selection of the camp site, must often yield to military necessity. The proper location of the camp is a matter of the greatest importance in maintaining the health and efficiency of troops, and demands intelligent and careful consideration. The site should be chosen with a view to the convenience of the command, should permit of ready internal communication, and should be located, if at all of a permanent character, near a road practicable for wheeled vehicles. Possible meteorological conditions should always be taken into consideration, and the locality should never be such as could receive the overflow of a watercourse or the surface drainage from high ground during rainstorms.

The desiderata in the selection of the camp site, from the standpoint of the line officer, are wood, water and grass—in abundance and of good quality. To these the sanitary officer will add dryness of soil and surroundings, elevation of site and protection from winds. No sanitary precautions can fully atone for the selection of an unhealthful camp site, even though they will do much toward the diminution of sickness, and hence the prompt reestablishment of a badly located camp in a more desirable locality is imperative. On the other hand, the best of natural sites will soon be defiled by lack of sanitary care, often resulting from inefficient policing. With the observance of proper sanitary regulations and a careful police, an originally good camping ground will continue to be healthful for a proportionately longer time.

Munson formulated the maxim that “if excreta are not moved or destroyed, the soldier must move, or he will be destroyed.” In the unsanitary ages, a moving command had better health than troops in permanent camps—because they left their excreta behind.

An abandoned camp site should never be utilized by another command, for the slightly greater labor involved in the clearing or arrangement of a new camp area is more than counterbalanced by the increased safety of the troops.

**Topography.**—While many factors combine to determine the healthfulness of localities, there are certain physical features of the surface of the earth, which, as shown by experience, may be accepted as fair indications of the salubrity of the location in which they occur. High ground should always be selected for the camp site: since not only is the surface drainage better, but exposure to air currents, as well as lessened atmospheric pressure, increases the rapidity of evaporation. Camps should never be located in ravines or the dry beds of water courses. Narrow, circumscribed valleys and punch-bowl depressions are, during warm weather, excessively hot during the night as well as by day. Ex-

posed ridges should be avoided in cool weather since they are constantly swept by chilling winds, but for that very reason they afford an excellent location for summer encampments.

An abundance of good water is of the first importance for troops,

FIG. 183.—CAMP OF A REGIMENT OF INFANTRY, WAR STRENGTH. (Field Service Regulations, U. S. A., 1914.)

and encampment in its vicinity is a necessity for a marching command, irrespective of the nature of the camp site and a possible exposure to malarial infection. Still, proximity to bodies of water does not necessarily render a locality unhealthful, and the bank of a lake or river, if not marshy, may make an excellent camp site. A guard should be set

over the water supply to prevent its contamination and improper use. All water supplies about the camp considered bad or doubtful should be labeled and a little methylene blue thrown into them. The soil should be porous and permeable, the ground water not nearer than six to eight feet from the surface.

Newly ploughed ground is not desirable for camping purposes, although a site which has long been under cultivation is usually healthful. All soil upon which the covering of turf has been destroyed is dusty in dry weather. Dusty camp sites are a nuisance and a menace to health. Camp grounds should be large enough to accommodate the command without crowding. The different organizations should be separated as far as military considerations and the available land permit, so as to discourage the spread of communicable disease, which is always to be guarded against. A brigade of 4,000 to 5,000 men is as large a force as it is desirable to put into one camp.

**Tentage.**—Tents are of many shapes and sizes, according to the use for which they are intended. The tent now most in favor with our army for commissioned officers is an oblong A-wall tent. For the men the pyramidal tent accommodates 8 men, or in emergency 12 men. It has arrangements for a tent stove and top ventilation. Modified designs are furnished for the mess tents, hospital tents, and also for use in the tropics. Tent flies make the tent cooler in summer and protect against rain and storms.

In general, the requirements of a good military tent are that it should not be of too great weight, should be quickly and securely pitched, and capable of being promptly taken down and packed for transportation. It should not be too large, yet, at the same time, must be of sufficient size to afford adequate air space; it should be durable, easily ventilated and aired, and possess stability in high winds. It should thoroughly protect the inmates from the inclemencies of the weather, and should be so shaped as to make all portions of the inclosed area of practical availability.

The material of which tents are made for the military service of the United States is 8, 10, and 12 ounce cotton duck. This is less costly than canvas, and is also less permeable to water and less liable to shrink in the presence of moisture. Linen tents, used in times past, have failed to give satisfaction. In European armies, however, hempen or linen canvas is usually preferred. In the German and other foreign services the material used for shelter is often artificially rendered waterproof, usually by treatment with acetate of aluminium.

The color of the 10 and 15 ounce duck tentage is of light drab or dusty brown, the glare of bright sunlight being thus greatly reduced and rendered much less trying to the eyes than in tents made of white canvas. Tents should be ditched. It is important to air and sun the

tents daily by raising the walls; it is also useful to move them a few feet to a new site so that the sunshine may dry and purify the old site; it is desirable while on the march to avoid recently used sites, since old latrines may be opened up.

In all armies the tent space afforded each man is very limited, and in our service the official tentage is not sufficient to meet the demands of hygiene. Hence it is fortunate that about  $\frac{1}{4}$  of the authorized occupants of a tent are, in practice, constantly absent. In France, the tent space is calculated at the rate of 11 square feet for each foot soldier and 28 square feet for each cavalryman. In our army, the allowance has varied with the tent employed, as well as with the conditions of climate and service. The United States infantryman, in the common wall tent, is entitled to 17 square feet upon which to dispose his person and equipment. Ground and air space being equal, the use of small tents is preferable to the employment of larger canvas; since, by the former, the danger of "crowd-poisoning" is much diminished by scattering the men, in smaller groups, more equally over the company area. Canvas tents are fairly permeable to air, except when wet, when ventilation becomes extremely faulty unless inlets and outlets are opened.

*Care of Tents.*—Tents should be ditched at once on pitching, else the floor may become flooded and bedding wet without a chance of drying for several days. The ground covered by the tent should be aired daily and the walls raised to let in the sun. In a permanent camp, tents are usually moved a short distance once a week, to a new site. Every day the bed sacks and blankets should be aired on the guy ropes and not on the ground. To insure ventilation, the tent door should not be closed entirely at night; canvas made damp by the dew at night is almost air-tight, and will interfere with ventilation.

*Temporary camps* are those designed for use over one night, or at most a short time. *Permanent camps* are used for ten days or more. A *bivouac*, or camp without shelter, diminishes the physical efficiency of troops, except for a few nights in fine weather. The sheltered tent is the only protection for soldiers on the march in campaign. Each soldier then carries a piece of canvas, a pole, and pins, which, when joined to a corresponding piece and pole from another soldier, makes an A-shaped tent, 84 inches long and 64 inches wide, sufficient for two men. One poncho is laid on the ground, and the other poncho and blankets are used for covers.

Latrines are placed on opposite sides of the camp from company kitchens, at a minimum distance of 50 yards from the company tents.<sup>7</sup>

Mess, store tents, and kitchen pits are located near the officers' line, and about 20 yards away. Hence, the mess tents and kitchen pits are at the opposite extremes of the encampment from the latrines.

<sup>7</sup> Appendix I. Field Service Regulations, U. S. A., 1914, p. 173.

## SANITATION OF BARRACKS AND CAMPS

Sanitation of barracks and permanent camps deals with sites, buildings, ventilation, lighting, heating and many other factors which have been discussed in other pages of this book. A camp or permanent garrison is a small compressed city, with a peculiar population constitution, consisting mostly of young adult males selected on account of health and physical fitness. Hence, a permanent army post should have an exceptional health record. The main factor to guard against is overcrowding. The principles of camp, post and barrack sanitation are the same as for other habitations.

Permanent garrisons should have complete water and sewage systems, either independent or connected with the neighboring city. Garbage and wastes are either burned or disposed of by the city authorities. Crude coal oil is used more and more for burning wastes, as well as for mosquito and vermin destruction.

Quarters and grounds must be kept clean and orderly at all times. This requires military policing. Careful watchfulness must be kept over the guardhouse, kitchen, mess halls, latrines, storage rooms, basements, picket lines, stables and other places to keep them from becoming dirty or infested with vermin.

Perhaps the most important room in the barracks is the general sleeping room, or squad room, as it is known. In this the soldier spends at least one-third of his time. Most of our barracks are now built to provide a floor space of 60 square feet and 720 cubic feet of air space per man. Foreign allowances are less. Thus, in Australia, it is 540 cubic feet; in Germany, 560 for cavalry, and 450 for infantry; English home station standards are 500 cubic feet.

There are three other buildings on a military reservation in which the sanitary officer is intimately concerned; namely, the hospital, the guardhouse, and the stable, also the kitchen, stores, latrines, etc. A regimental post with a population of about 1,200 persons has a hospital with a capacity of about 36 beds. Some of the things that the sanitary officer should inspect are the disposal of wastes, dust, cleaning of walks, elimination of weeds, privies and dumps, and inspection of the guardhouse, supervision of the mess and bakery, as well as of the hospital and the general health of the command.

The regulations prescribe bi-monthly examination for venereal diseases, and special reports of any outbreak of disease or other unusual incident likely to affect the health of the command. If an epidemic occurs he must notify the commanding officer in writing and forward one copy to the Surgeon General and another to the corps area or department surgeon. The local health authorities should also be notified.

Progress reports of the epidemic are included in the monthly sanitary report, which is made out in duplicate. The original copy, signed by the commanding officer, finally rests in the Surgeon General's office, the duplicate remaining on file as part of the medical history of the post.

**Water.**—Drinking water for the soldier needs the same supervision and purification as that for the civilian (see Chapter on Water). Permanent camps have a system of waterworks corresponding to towns.

FIG. 184.—ISHIJI FILTER (JAPANESE MODEL). (Keefer's "Military Hygiene," W. B. Saunders Co.)

Supplies for armies on the march and temporary encampments sometimes present unusual difficulties.

A soldier needs at least three quarts daily for drinking and cooking, and another three quarts for washing. These are minimum amounts. This must be increased by one-third or one-half in the tropics. In permanent garrisons at least thirty gallons per capita per day should be provided. Ten gallons of water per capita per day without sewers presents a serious problem in disposal.

While on the march it is important that a medical officer, well in the van, make a sanitary survey of all available water supplies, which may be supplemented by a few simple field tests. All wells, springs, streams, etc., should be plainly labeled before the command arrives. When a stream is reached it is usually crossed, for tactical reasons, if a

halt is desired at that point. When the encampment is on the bank of a stream it should at once be policed in such a way that water for drinking and cooking is drawn farthest up stream, that for bathing and laundering farthest down stream, while animals are watered between. If it is desired to fill canteens it is best to provide small excavations for that purpose, otherwise the water will soon be rendered muddy, making it undesirable for those farthest down the bank.

*Boiling.*—The supply for the day may be boiled in covered kettles at night, so that it may be cool by morning. Or each soldier may boil his

FIG. 185.—1. The filter cage with the cloth covering. 2. The filter cage without the cloth covering. All the parts of the apparatus "rest" in the largest can, and this is transported in the crate. (Wilson's "Field Sanitation," George Banta Pub. Co.)

individual supply in the canteen. Boiling is a safe and satisfactory method of rendering water safe. In the exigencies of military service boiling is not always practical, and when resorted to must be carefully supervised.

The Forbes-Waterhouse Sterilizer is based upon the heat exchange principle. Crude oil or solid fuel, however, is necessary to supply the heat. Moreover, the outfit when packed is heavy and bulky and not always reliable, and has therefore been discontinued in our army.

*Distillation.*—Distillation is mostly confined to marine use.

*Filtration.*—Filtration is often necessary to clarify a water, but except under unusually favorable circumstances cannot be depended upon under military conditions to render a water safe. The British and French troops both use water carts holding one hundred gallons, furnished with a Pasteur filter. The filters clog readily, break often, and the

arrangement is not wholly satisfactory. The Japanese made use of the Ishiji filter in the war with Russia, based on the principle of mechanical filtration (page 1122). It consists of a conical canvas reservoir supported from a tripod, and having two canvas lugs near the bottom which hold charcoal and sponge. Alum is used as the coagulant.

The Darnall filter used in our army is also based upon the principle of mechanical filtration. It consists primarily of a reservoir and a siphon, the immersed end of which is armed with a wire cage over which Canton flannel is wrapped as a filtering material. This siphon is cleansed with boiling water and primed with a small pump. The water to be filtered is first treated with the coagulant—alum and sodium carbonate in the ratio of one pound per five hundred gallons. The bacterial efficiency is about ninety to ninety-five per cent. The Darnall filter can filter two hundred gallons every four hours; it weighs fifty-two pounds. It should not be depended upon to do more than clarify the water, which may then be purified with chlorinated lime.

The Darnall filter has been extensively used throughout the United States Army. It is the most easily managed and transported of any of the modern field appliances for clarifying turbid water, for which it is especially applicable. Fig. 185 shows the construction and operation of this filter.

*Chemical Disinfection.*—The best chemical with which to purify water is bleaching powder—chlorinated lime (page 1132). A very muddy water may first be filtered. The manner of “chlorinating” water in our army is by the use of the Lyster bag. This consists of a waterproof canvas bag holding forty gallons, with five faucets near the bottom, so that the entrained sediment will not be drawn off. A glass ampule holding one gram of chlorinated lime is broken into a little water and this poured into the bag. This is in the proportion of one part of chlorinated lime to 150,000 parts of water; in terms of available chlorine, one part to 300,000—otherwise expressed as 3.3 parts per million. At least half an hour should elapse before canteens are filled from the faucets.

The British in the World War used a 100-gallon metal tank on two wheels, to which twenty-five grams of hypochlorite were added. Water is collected from indicated sources, and allowed to stand over night with its charge of “bleach.” The French water cart is made up of two barrels on a pushcart, or may be horse drawn. The water is also disinfected with bleach. In addition both forces analyzed the water of springs, wells, streams, etc., which were then labeled as potable or non-potable. The sanitary analysis consists chiefly of determining the chlorids and intestinal bacteria. The United States water wagon holds two hundred and twenty-five gallons and has a pump for filling.

For water-borne diseases and other considerations concerning drinking water see Section VIII.

**Disposal of Excreta.**—For the prevention of typhoid fever, dysentery, hookworm and other infections it is of prime importance that the urine and feces be disposed of in a safe and satisfactory manner. Of all camp wastes the discharges from the body have the greatest sanitary significance. For permanent garrisons, sewerage systems with water carriage are possible and desirable. For temporary encampment, burial or burning are the most satisfactory methods.

Various types of incinerators for this purpose have been designed, such as the Lewis and Kitchen, and the McCall incinerators, but they are clumsy, heavy, and, unless carefully tended, prone to become nuisances.

FIG. 186.—CONSTRUCTION OF PIT LATRINE. (Munson's "Military Hygiene," Wm. Wood & Co.)

The best method is to burn the material with crude coal oil, which is simply poured into the pit and lighted. This should be done daily. In firing, some straw or other light combustible stuff should first be thrown in.

**Latrines.**—The best design is the Havard latrine box. The seats are arranged so that they are always closed save when in use, and are in pairs, back to back. The box should be lightproof and fly-tight, and should completely cover the pit, which is ten feet deep by six feet wide; the length depends upon the number of seats. The pit is edged with a board frame on which the latrine box rests. It is preferable to dig the pits in pairs, so that the latrine box can be in use while the other pit is being burnt out. The pit is so deep that the board frame is not affected by the fire, and the flame is hot enough to consume the material with little or no odor. After the burning, lime may be sprinkled into the pit, depending upon circumstances.

Latrines should be ditched to prevent flooding and screened for privacy; also roofed against rain. Separate urinals should be provided

in order to prevent soiling the seats and also for the purpose of reclaiming the ammonia.

The urinal can is an ordinary galvanized iron can issued by the Quartermaster's Department. If such a can is not available, ordinary coal oil tins will suffice. The cans are placed in the company streets at

FIG. 187.—STRADDLE PIT COVER. (Wilson's "Field Sanitation," George Banta Pub. Co.)

retreat. They should be emptied each morning at reveille into the sink or the incinerator and then thoroughly cleaned and put in the sun during the day. Two or three times each week the cans should be burned out with a handful of straw and some coal oil. The position of the cans should be marked at night, with a lantern, and the ground where

FIG. 188.—PIT CREMATORY. (Wilson's "Field Sanitation," George Banta Pub. Co.)

the cans stand should be burned over each day. It is good practice to spread latrines once daily with a mixture of kerosene and lamp black.

In the absence of oil, and especially on the march, the "straddle pit" is used. This is simply a narrow deep trench, which should be covered and marked on leaving. The straddle pits are recommended for camps

of one night. The straddle pit is simply a shallow trench less than two feet deep and is used by the men astride. It is easily and quickly made, and by reason of its slight depth permits more rapid disintegration of the excreta and is easily filled on breaking camp. Accommodations should be provided for 5 per cent. of the command.

A cover for the straddle pit, devised by Major R. U. Patterson, of the United States Army, is shown in Fig. 187. It is arranged for two. The lid for each opening falls unless held open. This cover only requires a little lumber and four strap hinges.

All camps, both temporary and permanent, must be policed to prevent

FIG. 189.—PIT FOR KITCHEN REFUSE. (Wilson's "Field Sanitation," George Banta Pub. Co.)

nuisances. Discipline concerning latrines and their use is a very important factor in camp sanitation. See also Section IX.

The following rules should be enforced for the care of the "sink": it should be screened with brush; it should be covered with a tent fly; it should have a light at night; each man should cover his deposit with earth by means of a scoop; it should be burned out daily with straw and coal oil; it should have a comfortable seat and a good receptacle for toilet paper; the ground in front should be attended to, as it is apt to be fouled with urine; the sink should be ditched; a man should be detailed to see to it that these measures are carried out.

**Disposal of Garbage.**—The only satisfactory method of disposing of garbage under camp conditions is by burning; if this is not practical it may be buried and well covered. No other method should be countenanced. Expensive crematories are unnecessary, for simple devices serve every purpose. Each mess should incinerate its own garbage

promptly. Garbage burns more readily if the solids are separated from the liquid, which may be done by a sieve-covered can.

Wastes from the kitchen are both liquid and solid and are often disposed of separately. On the march and in a temporary camp, liquid waste, such as dish water, is best disposed of by digging a pit in the ground near the kitchen, and when possible filling it half full of stone. A cover should be placed over the pit to prevent accidents, and further, it should be screened against flies. The cover should be made so that

one portion can be removed and the kitchen slop poured into the pit through a strainer or screen of wire. The dimensions are about 4 x 4 x 6 feet deep. Only liquid waste should be poured into this pit. The solid matter should be burned in the kitchen fire.

Another arrangement for a pit to dispose of kitchen refuse is shown in Fig. 189. This is particularly useful in sandy soil. The garbage is poured into the inner can, the bottom of which is a strainer. From time to time the solid portion of the garbage remaining in the inner can should be burned in the kitchen fire.

The garbage can requires especial attention. The cover must fit properly and always be in place except when it is being filled or cleaned. The

URINE SOAKAGE PIT

FIG. 190.

outside of the can must be clean at all times, and it is best to have it stand on a platform, in order to facilitate emptying and to prevent a nuisance under the can. The inside of the can may be purified by burning it out with coal oil, straw or paper. The ground around the can or barrel often becomes polluted, and hence an excellent place for the breeding of flies and the production of disagreeable odors. To remedy this condition, scrape the ground around and under the can, spread hot ashes over the area scraped, and occasionally burn over the area with coal oil. On no account should cooks be allowed to sprinkle lime on the ground around the camp to take the place of cleanliness and save the labor of policing.

The *rock pile crematories* are the best garbage incinerators for camps. They are all based upon the same principle, but it is unusual to find any two quite alike. Essentially, they consist of a pile of embers for cremating the heavier portions of the garbage, and the fire is placed against a pile of rocks which, when hot, volatilize and consume the liquid por-

FIG. 191.—A ROCK PILE CREMATORY.

tion. The designs vary from circular as shown in Fig. 191, to horse-shoe-shaped, with or without a stone bottom.

In the circular rock pile crematory the fire is built in one quadrant, into which solid wastes are thrown. The central pile of rocks helps in creating a draft and also offers a larger surface for evaporating liquids,

FIG. 192.—U. S. ARMY GREASE TRAP.

which are thrown into neighboring quadrants. Garbage will burn itself, once the fire is well started, or it may be assisted with coal oil or other inflammable material. Unconsumed particles together with the ash should be scraped up and burned every morning by the kitchen detail.

When fuel is scarce and stones few, probably no device for the destruction of garbage and refuse is more readily improvised than the

Caldwell or English crematory. It consists of a trench ten feet long and one foot wide and about fifteen inches deep at the middle and thence gradually shallowing up at each end to the surface level. Over the deep part a barrel is placed and around it is constructed a chimney five feet high, of clay, earth or sod, sprinkled with water and packed tightly. Two openings at the bottom are provided for draft. A fire is made in the interior and the barrel burned out, after which there remains a solid cone of earth. Fuel and garbage are dropped down the chimney. Of the two openings the one to leeward is closed. A bed of tin cans is a fair substitute for a grate. See also Section X.

### SANITATION OF TRENCHES

The sanitation of trenches, such as are used in modern warfare, presents unusual difficulties. Owing to the extended use of hand grenades, trenches are dug deep enough so that the soldier's head is several feet below the surface. Parts of trenches may be 40 feet below the surface. Trenches are usually one to two meters wide and often contain dugouts for shelter, protection and other purposes. Connecting laterals communicate with the reserve trenches in the rear. Ordinarily one man per square meter is stationed in the first line trench, which is increased to four or five in time of attack.

In low wet ground, or in rainy weather, water collects and must be pumped out or drained. The trenches may be floored or lined with wood, cement, or other available material.

Rats are a particular nuisance in trenches used for any length of time; for their suppression see page 338. Flies abound, owing to dead bodies in "no man's land" between the opposing lines, and also from horse manure. Flies were held to be responsible for much of the gastrointestinal disorders among the troops in the World War. Lice and other vermin may infest the trenches.

Latrines are placed in covered recesses or in dugouts a short distance to the rear of the trenches, and connected by a narrow passage. Lime and sulphate of iron are used plentifully to cover excreta, the latter if it is to be used as fertilizer; it is better, however, systematically to collect, burn or bury such material. All forms of trench trash and débris are collected in sacks and carried to the rear frequently.

Provisions are made all along the line for daily baths so far as possible, and tubs, improvised showers or designated streams are used for this purpose.

Commands are relieved from trench duty as frequently as exigencies permit. The usual tour of duty is 48 hours. Despite the unfavorable conditions there has been surprisingly little sickness. Epidemics have

been rare and mild. An unusual number of cases of psychoses developed in the first part of the trench war, but the mentally unfit were soon weeded out.

Many trenches, especially in France, are dug in land that has been intensively cultivated for centuries, hence infections such as tetanus and the gas bacillus (*B. welchii*) frequently complicate wounds.

## HYGIENE IN THE TROPICS

The chief characteristics of tropical climates which adversely affect military service are the constant warm temperature, great relative humidity, high degree of insolation, close contact with populations having low sanitary standards, and prevalence of unusual preventable infections. Our own tropical possessions, such as the Philippines, Porto Rico, Hono-

FIG. 193.—IMPROVED ICE-BOX. (Wilson's "Field Sanitation," George Banta Pub. Co.)

lulu, and the Canal Zone, have better climatic conditions than continental regions like India, South America, and northern Australia. In Manila the mean temperature for May, the hottest month, is 84.5° F.; in the Philippines 92° F. in the shade represents a hot day. The discomforts, in Cuba, Porto Rico, and the Philippines, of the constant warmth and humidity are greatly alleviated by the almost incessant blowing of trade winds or monsoons. In these parts heat exhaustion is rare; sunstroke is practically unknown. While the heat and high humidity of our tropical possessions exert an enervating influence, it is believed that the

ill effects have been greatly exaggerated. Psychological influences, such as fear of disease, dislike of the service, homesickness, monotony of life, enormous distance from home and friends, and lack of social opportunity, rather than the climate, favor mental deterioration and recourse to liquor and prostitutes.

If proper care is taken, with sufficient exercise and good habits, it is as easy to remain in good health in the tropics as in temperate regions. A few special precautions are necessary to avoid endemic disease.

FIG. 194.—WATER BAG TO COOL WATER IN HOT COUNTRIES. The bag should be hung in the breeze; the cooling depends upon evaporation. (Wilson's "Field Sanitation," George Banta Pub. Co.)

I can vouch for the fact that it is quite practical to do hard mental work in the tropics for a year or more. However, prolonged residence seems to bring on lassitude and a disinclination for both mental and physical exertion. Hence, it is customary in our Government Service to limit tours of duty in the tropics to a period not exceeding three years at a time.

When a choice is possible, residence or camp site in the tropics should always face the trade winds. The site should be high and dry and removed from native quarters in order to avoid infections. Houses and tents must be screened, and in addition a mosquito bar for the bed is advisable. Houses should be built on piers or piles well above the ground. Where ants abound, the legs of beds and food chests should stand in water, but care must be taken that this water does not become a breeding place for mosquitoes. Special care should be taken to remain in the security of a well-screened abode from before sunset until after sunrise.

It is advantageous to avoid the direct sun at noon; otherwise it is best to wear a pith helmet or carry a green parasol. Colored glasses against the glare of the sun are a comfort. The clothes should be white or khaki color, light and airy, and of the best of linen. The diet in the tropics should not differ materially from that in temperate climates—about the same number of calories are required, and it is not possible to regulate heat production and heat loss through diet. Overeating is more apt to bring on gastro-intestinal troubles in hot weather than in cold. Special care must be taken to see that the diet is well balanced and contains sufficient vitamins.

It is safest to eat only well-cooked food and to drink only boiled water, unless assured of their quality. More water should be drunk in

hot climates to make up for the unusual evaporation. Alcohol especially must be avoided in the tropics.

The skin should be kept clean, and care taken to prevent the effect of prickly heat.

It is a great mistake to avoid exercise in the tropics. Tennis, golf, horseback riding or walking in the cool of the evening or morning are helpful. Swimming is an unusually good form of exercise in the tropics, provided the waters are clean and safe.

It will be necessary to have an ice-box, not alone for food, but for serums, vaccines, and other supplies which are ruined by heat.

A temporary ice-box on the march and in temporary camps may be made simply by digging a hole in the ground and wrapping the meat and ice in a shelter tent or poncho—obviously not a very satisfactory arrangement. In 1892, while in Camp Jenner, I succeeded in keeping supplies cold and clean during the hot summer on the Rio Grande by sinking boxes in the ground with an air space between. This arrangement is shown in Fig. 193, taken from Wilson's "Field Sanitation." This ice-box should have a double lid. The air space between the two boxes may be packed with hay or sawdust. Drain holes should be placed in the bottom.

## COLD CLIMATES

Ordinarily, troops stationed in Arctic regions maintain a higher average of health than those remaining in the temperate zone. Great cold at many times has been a big factor in military operations. Perhaps the most notable example is the celebrated retreat from Moscow. On the march in cold weather straggling must never be permitted. Tight shoes, or anything which slightly restricts the circulation, greatly increases the liability of frost-bite. Snow-blindness is common among soldiers in the northwestern part of the States as well as in Alaska. It may be prevented by wearing colored goggles, with a felt border to prevent freezing to the face. The so-called "snow eyes" of the Eskimo are even better. They consist of a light wooden spectacle with a narrow slit to look through. Anything which constricts the circulation must be avoided, especially in cold climates. In our army, woolen outer and under garments are supplied for service in the north and cotton for the south and the tropics. In very cold weather the canteen, filled with boiling water, makes a very fair hot-water bag.

## SECTION XVI

### A LABORATORY COURSE IN PREVENTIVE MEDICINE AND HYGIENE

Following is a schedule of the laboratory course used in the Department of Preventive Medicine and Hygiene of the Harvard Medical School. The course must coördinate with other Departments, and will therefore vary in different Medical Schools.

The required exercises and approximately the time for each are as follows:

SUBJECT	TIME PERIOD
Vaccination	1
Phenol coefficient	1
Water, chemical	2
Milk, bacteriological	1
“ chemical	1
Bacterial vaccine	1
Vital statistics	1
Schick test and diphtheria diagnosis	1
Pneumococcus typing	1
Meningococcus carriers	1

(A period is from 3 to 5 P. M.)

The following optional exercises are offered:

Air analysis  
Room fumigation  
Water, bacteriological  
Examination sputum for tubercle bacilli  
“ smears for gonococci  
“ feces for typhoid bacilli  
Blood grouping on basis of iso-agglutinins.  
Sanitary Excursions

Each laboratory exercise must be written up, showing how the results were obtained, with an interpretation.

Students may supply their own sample of milk, water, etc., for sanitary analysis.

The laboratory is open for any student who wishes to repeat an exercise, or do additional work connected with his sanitary survey, or other problem in Preventive Medicine. Assistance will be given. Apply to the Instructor.

## I

## VACCINATION

(*Vaccinia—Cowpox*)

Students will vaccinate each other, and each student will keep a careful clinical record of his own local and general reactions.

Keep a daily record of temperature, pulse, etc., on the enclosed chart. Fill in blank below and make a daily record of (1) local eruption, with sketches showing size, number, color, appearance, and development of papules, vesicles, pustules and areola; (2) constitutional symptoms, enlargement of lymph nodes, etc. Students are advised to make blood counts, urine examinations, and other laboratory tests.

Indicate in conclusion the type of reaction, whether primary, accelerated, immediate, or negative.

## VACCINATION RECORD

Name	Age	Sex
Operator	Date	Hour M.
Vaccine: Produced by	U. S. License No.	Lot No.
History of Previous Vaccinations:		
	1st	2nd 3rd
(1) Age		
(2) Method		
(3) Result		
(4) Sketch of previous scars		

Clinical Study of Present Vaccination: (a) Daily record local eruption, etc.

(b) Constitutional symptoms. Record temperature, pulse, etc. on enclosed chart.

(Use extra sheets if necessary)

Summary and Diagnosis:

## OTHER TESTS

Immunity or susceptibility to diphtheria as determined by the Schick test will be given in a separate exercise.

Students are also offered opportunity to immunize each other with the triple typhoid vaccine.

Opportunity will be given to test sensitiveness to various food proteins, pollens and other antigens.

Accurate clinical records must be made in detail of the course of events of each test made. These records should be inserted in the notebook.

## II

### STANDARDIZATION OF DISINFECTANTS

#### *Phenol (Carbolic) Coefficient*

**Object.**—To compare the germicidal power of an unknown disinfectant against that of a 1 per cent. solution of phenol.

Make up, according to directions, two dilutions of phenol, and three of the unknown disinfectant, from the following table:

From a 5 per cent. solution of phenol

10 c. c. plus 35 c. c. water = 1:90

10 c. c. " 40 c. c. " = 1:100

From a 1 per cent. solution of the unknown disinfectant

10 c. c. plus 12½ c. c. water = 1:225

10 c. c. " 15 c. c. " = 1:250

10 c. c. " 17½ c. c. " = 1:275

Bring the water bath to 20° C. The thermometer should be in a test tube, partly filled with water, in the bath. Place the suspension of *B. typhosus* in the bath to allow the clumps to settle and the temperature to reach 20° C. Place the 5 large sterile test tubes in their places in the water bath.

Transfer 5 c. c. of the phenol dilution (1:90) to the first large test tube on the left of the water bath. Rinse the pipet in the next dilution (1:100) and transfer 5 c. c. of it to the next tube in the water bath. With another pipet, transfer 5 c. c. of the dilutions of the unknown disinfectant to the remaining three large test tubes, working from left to right.

Flame both platinum loops. Add 0.1 c. c. of the culture to each of the 5 large tubes at exactly 30-second intervals, beginning at the left, and taking care that the culture does not get on the walls of the tube. Mix contents of tubes after adding cultures.

Thirty seconds after inoculating the last large tube, start to transfer a loopful from each large tube in the water bath to culture tubes in the rack, and continue without interruption at intervals of 30 seconds until all the transfers have been made. The platinum loops are flamed and used alternately. Label the first tube of each row with the disinfectant and dilution. Incubate for 48 hours and tabulate results.

## EXAMPLE

Time in Minutes			2½	5	7½	10	12½	15
Phenol	1-90	.....	+	—	—	—	—	—
Phenol	1-100	.....	+	+	—	—	—	—
Unknown	1-225	.....	+	—	—	—	—	—
Unknown	1-250	.....	+	+	+	—	—	—
Unknown	1-275	.....	+	+	—	+	—	—

The carbolic coefficient is therefore  $\frac{225}{90} = 2.50$ .

Record results and state the limitations of the test as applied to the value of a germicide in practical application.

## III

## WATER

## EXERCISE 1

**Object.**—To determine various kinds and degrees of pollution.

**Free and Albuminoid Ammonia.**—Wash flasks and Nessler jars with distilled and ammonia-free water. Measure out 500 c. c. of the sample and pour into flask.

Connect flask to condenser and light burner, adjusting so that the Nessler jars fill in from 5 to 8 minutes.

Distill over three jars of 50 c. c. each.

Turn out flame and disconnect flask. Add 40 c. c. alkaline permanganate solution (hot) and continue distillation until 5 more jars are collected. Measure into Nessler jars from buret the following amounts of ammonium chlorid standard: 0.3, 0.5, 0.7, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5 c. c., and dilute with ammonia-free water to the 50 c. c. mark. To each of the eight jars collected, and to each standard jar, add 2 c. c. of Nessler solution. DO NOT MIX. Allow to stand ten minutes. Compare each jar distilled over with the standards, and record the number of c. c. of ammonia in the standard which it matches. For example, if jar No. 1 matches the jar containing 1.5 c. c. of the standard, record it as 1.5. Add together the results from the three jars for free ammonia and multiply by 0.02 to get part per million of N as free ammonia. Do the same for the five jars distilled for albuminoid ammonia.

## EXAMPLE

N as Free $\text{NH}_3$	N as Albuminoid $\text{NH}_3$
Jar 1 — 1.5	Jar 4 — 1.7
" 2 — 0.3	" 5 — 0.8
" 3 — 0.0	" 6 — 0.5
—	" 7 — 0.3
$1.8 \times 0.02$	" 8 — 0.3
= 0.036 part per million	—
	$3.6 \times 0.02$
	= 0.072 part per million

Record results and give interpretation.

## EXERCISE 2

**1. Nitrate Determination.**—Measure exactly 20 c. c. of the sample into a small evaporating dish. Put on the water-bath and evaporate nearly to dryness. Allow the last few drops to evaporate at room temperature. Add 1 c. c. of phenol di-sulphonic acid from the buret and rub up thoroughly with a rod. Add about 10 c. c. of distilled water and make alkaline to litmus paper with ammonium or potassium hydrate. Wash into a Nessler jar and dilute to the 50 c. c. mark with distilled water. Compare with standard nitrate solution as follows: Fill a 50 c. c. graduate with the standard nitrate solution and pour into a clean 100 c. c. Nessler jar until the color matches the sample. Note amount of standard used and record. (Or compare with a series of standards.)

To find parts of N as nitrates per million, divide the number of c. c. of standard by the number of c. c. of sample used.

Record results and give interpretation.

**2. Determination of Nitrites.**—Fill a Nessler jar up to the 50 c. c. mark with the sample. To the sample add 1 c. c. of sulphanilic acid and 1 c. c. of alphanaphthylamin solution from the burets. MIX THOROUGHLY. Allow to stand not less than 10 minutes nor more than 30. Compare sample with standards and record in terms of c. c. of standard nitrite solution. To get parts of N as nitrites per million, multiply the number of c. c. of the standard by 0.01. The color is due to the formation of azobenzolnaphthalaminsulphonic acid.

Record results and give interpretation.

**3. Determination of Chlorids.**—Measure out 50 c. c. of the sample into the evaporating dish. Into another measure 50 c. c. of distilled water. Add to each 1 c. c. of the potassium chromate indicator. To the sample add carefully from the buret standard  $\text{AgNO}_3$  until the red of the silver chromate persists, using the distilled water for comparison of colors. Record number of c. c. of the standard  $\text{AgNO}_3$  solution used. Each c. c. of the standard equals 0.0005 gram of Cl, or

0.5 mg. of chlorid. The number of c. c. of the standard used times 0.5 equals mg. of chlorid in 50 c. c. of the sample. This result times 20 equals mg. per liter or parts per million.

Record results and give interpretation.

**4. Determination of Hardness.**—Into the glass stoppered bottle measure 50 c. c. of the sample. From the buret add standard soap solution 0.3 c. c. at a time. After each addition shake thoroughly, and lay the bottle on its side. When the lather covers the entire surface and persists for five minutes, read the buret and record. Now add 0.5 c. c. of the soap solution. Shake, and if the lather disappears add more soap as before until a lather is obtained which persists for five minutes. The magnesium salts are precipitated first, then the calcium salts; hence the second addition of soap solution after five minutes, which will indicate the presence or absence of calcium hardness. If the lather does not disappear on the addition of the 0.5 c. c. of soap solution, the first reading is the end point. Read the parts per million from the table of hardness and convert into degrees of hardness Clark's scale from the conversion table.

Record results and give interpretation.

TABLE OF HARDNESS SHOWING THE PARTS PER MILLION OF CALCIUM CARBONATE FOR EACH 0.1 C. C. SOAP SOLUTION WHEN 50 C. C. OF SAMPLE ARE USED

C. c. of Soap Solution	0.0 c. c.	0.1 c. c.	0.2 c. c.	0.3 c. c.	0.4 c. c.	0.5 c. c.	0.6 c. c.	0.7 c. c.	0.8 c. c.	0.9 c. c.
0.0								0.0	1.6	3.2
1.0	4.8	6.3	7.9	9.5	11.1	12.7	14.3	15.6	16.9	18.2
2.0	19.5	20.8	22.1	23.4	24.7	26.0	27.3	28.6	29.9	31.2
3.0	32.5	33.8	35.1	36.4	37.7	38.0	40.3	41.6	42.9	44.3
4.0	45.7	47.1	48.6	50.0	51.4	52.9	54.3	55.7	57.1	58.6
5.0	60.0	61.4	62.9	64.3	65.7	67.1	68.6	70.0	71.4	72.9
6.0	74.3	75.7	77.1	78.6	80.0	82.4	82.9	84.3	85.7	87.1
7.0	88.6	90.0	91.4	92.9	94.3	95.7	97.1	98.6	100.0	101.5

CONVERSION TABLE OF HARDNESS

	Parts per Million	Clark Degrees	French Degrees	German Degrees
Parts per million.....	1.00	0.07	0.10	0.056
Clark degrees.....	14.3	1.00	1.43	0.80
French degrees.....	10.0	0.70	1.00	0.56
German degrees.....	17.8	1.24	1.78	1.00

English degrees of hardness (Clark's scale) represent grains of calcium carbonate per imperial gallon.

French degrees of hardness represent parts per 100,000 of calcium carbonate.

German degrees of hardness represent parts per 100,000 of calcium oxid.

To convert hardness from one scale to another, multiply by the factor opposite the scale in which it is expressed and under the scale to which it is to be converted.

The temporary hardness is due usually to bicarbonates of calcium and magnesium; the permanent hardness is due to sulphates and chlorides of these elements.

## IV

### MILK

**Bacteriology of Milk**—*Object*.—To determine the sanitary character of a milk.

1. Mix milk by shaking the bottle.
2. Flame lip of bottle and pour a sterile test tube about half full of milk for B. Welchii test. Put test tube into water-bath at 80° C. for an hour. Incubate this for 24 to 48 hours at 37° C.
3. Pour about 50 c. c. milk into sterile bottle for bacteriological work.

4. Put agar on to melt.
5. Label Petri dishes: 1/100, 1/1,000, 1/10,000 in duplicate, together with name and date.
6. With first 1 c. c. pipet:
  - (a) Put 1 c. c. milk into 99 c. c. water blank; shake 25 times = 1/100 dilution.

With second pipet, put:

- (a) 1 c. c. of 1/100 dil. into 9 c. c. water blank = 1/1,000 dilution.
- (b) 1 c. c. 1/100 dil. into 99 c. c. water blank = 1/10,000 dilution.

(c) and (d) 1 c. c. 1/100 dil. into 2 Petri dishes.

With third pipet, put:

(a) and (b) 1 c. c. 1/1,000 dil. into 2 Petri dishes.

With fourth pipet, put:

(a) and (b) 1 c. c. 1/10,000 dil. into 2 Petri dishes.

Before plating each dilution, rinse pipet by drawing dilution to be plated back and forth in the pipet several times.

7. Cool agar slightly by adding cold water to cup. Cool each tube to about 45° C.; test by placing tube against cheek; flame lip of tube and pour. Revolve plate. Allow to cool while doing other tests. When hard place upside down in incubator. Plates should be read in 24 to 48 hours.

8. Empty dilution bottles and put pipets in pan.

## MICROSCOPIC EXAMINATION OF BACTERIA IN MILK

**Breed Method.**—1/100 c. c. milk or cream is spread with needle over area of a square centimeter. Film allowed to dry. Fix in methyl alcohol, extract fat in ether. Stain in Loeffler's methylene blue to desired intensity. Extract any excess stain in the preparation by dipping in 95 per cent. alcohol. It is necessary to know the area of microscopic field at any given tube length, and this may be determined by a stage micrometer. Using oil immersion lens, count organisms in field of known area. To make this comparable to agar plate count, groups of organisms of same kind are counted as one. Count from ten to fifty fields in this manner and determine average. Then if the area of each field counted is, for example, 1:4,000 of a square centimeter, then the final count in 1 c. c. would be  $X$  (the average for each field) multiplied by 4,000, multiplied by 100 (the amount of milk taken). This method is very valuable in determining the condition of milk previous to pasteurization. Results may be obtained in two or three hours, and in raw milk they agree closely with plate count.

**Slack's Method** (demonstrated).—A definite volume of milk is sedimented. This sediment is spread on a slide, stained as described under the Breed Method, and examined. A total count is obtained which is approximately quantitative. This method is valuable in classification of milks on basis of presence or absence of streptococci or other organisms of characteristic morphology.

## BACTERIOLOGICAL MILK STANDARDS

*Certified, or Grade A* (raw milk).—Not over 10,000 per c. c.

*Grade A* (pasteurized milk).—Not over 200,000 per c. c. before pasteurization, and not over 10,000 per c. c. after pasteurization.

*Grade B.*—Not over 1,000,000 per c. c. before pasteurization and less than 50,000 per c. c. after pasteurization.

*Cream.*—In 20 per cent. cream the count shall not be more than five times the limit for the same grade of milk.

1. **Fat Test.**—Milk should be well mixed by pouring (not shaking) immediately before each of the following tests:

Pipet into the Babcock flask 17.6 c. c. of the sample of milk. Pipet 17.6 c. c. of  $H_2SO_4$  (sp. gr. 1.82) into the flask (properly balanced) and revolve on centrifuge for five minutes. Remove flask and add hot water up to the mark at the bottom of the neck and whirl for three minutes. Remove again and add hot water up to the 8 mark in the neck. Whirl again for one minute. Remove and, with the calipers, immediately read the percentage of fat. Empty the flask and rinse with hot water before the contents get cold.

2. **Specific Gravity.**—Mix the milk thoroughly by pouring and fill the cylinder. Take the specific gravity with the Quevenne and New

York Board of Health lactodensimeters. Record temperature and specific gravity. Correct each determination for temperature by the table. (Accepted temperature for sp. gr. is 60° F. or about 15° C.)

**3. Total Solids.**—Richmond Slide Rule. Bring the observed lactometer reading opposite the 60° mark and read the correct specific gravity opposite the observed temperature. The arrow of the slide is then set opposite the observed percentage of fat and the total solids are read opposite the corrected specific gravity on the scale marked "specific gravity."

TABLE FOR CORRECTING THE SPECIFIC GRAVITY OF MILK ACCORDING TO TEMPERATURE.  
(Adapted from Table of Vieth.)

Specific Gravity	10°	11°	12°	13°	14°	15°	16°	17°	18°	19°	20°
1.027	26.1	26.2	26.4	26.5	26.7	26.9	27.1	27.4	27.5	27.7	28.0
28	27.0	27.2	27.4	27.5	27.7	27.9	28.1	28.4	28.5	28.7	29.0
29	28.0	28.2	28.4	28.5	28.7	28.9	29.1	29.4	29.5	29.8	30.1
30	29.0	29.1	29.3	29.5	29.7	29.9	30.1	30.4	30.5	30.8	31.1
31	29.9	30.1	30.3	30.4	30.6	30.9	31.2	31.4	31.5	31.8	32.2
32	30.9	31.1	31.3	31.4	31.6	31.9	32.2	32.4	32.6	32.9	33.2
33	31.8	32.0	32.3	32.4	32.6	32.9	33.2	33.4	33.6	33.9	34.2

Directions: Find the observed gravity in the left-hand column. Then, in the same line and under the observed temperature will be found the corrected reading.

TEMPERATURE CONVERSION TABLE

C.	F.	C.	F.
9°	48.2°	15°	59.0°
10°	50.0°	16°	60.8°
11°	51.8°	17°	62.6°
12°	53.6°	18°	64.4°
13°	55.4°	19°	66.2°
14°	57.2°	20°	68.0°

To change degrees C. to degrees F. =  $(C.^{\circ} \times 915) \div 32$   
 " " " F. " " C. =  $(F.^{\circ} - 32) \times 5/9$

#### 4. Milk Standards.—

	Butter Fat	Solids Not Fat	Total Solids
U. S. Government.	3.35	—	12.0
Boston, Mass. ....	3.25	8.5	—

In general, the following may be applied to the interpretation of results of chemical examination of milk:

*Normal Milk.*—Ratio of fat to total solids about as indicated in Standards:

$$3.25 : 12 = 1 : 4 \text{ (approximately)}$$

*Skim Milk.*—Ratio of fats to total usually more than 1 : 4.

$$0.8 \text{ per cent. (fat)} : 9.3 \text{ per cent (total solids)} = 1 : 11$$

*Watered Milk.*—Ratio of fat to total solids about as in normal milk, but actual amount of each low. Solids not fat usually below 8.0.

2.1 per cent. (fat) : 9 per cent. (total solids) = 1 : 4 (approximately)

*Skimmed and Watered Milk.*—Low fat, low solids not fat, and ratio of fat to solids usually greater than 1 : 4.

1.2 per cent. (fat) : 8.5 per cent. (total solids) = 1 : 7

In the last two types of adulteration a determination of refractive index is valuable in drawing conclusions.

## V

### BACTERIAL VACCINE

#### *Alternative Methods Will Be Demonstrated*

1. Set up water bath to each 2 men and accurately regulate to 53° C.

2. Clean slides for smears.

3. Make bacterial suspension with 1 c. c. ungraduated pipet using about 1 to 2 c. c. salt solution and reserve drop in pipet for Par. 4. Heat suspension for one-half hour in water bath. Boil large rubber nipple ten minutes.

4. Put grease pencil mark on capillary pipet about one inch from end. Draw citrate solution to the mark, allow a *small* bubble of air to enter, draw up a measure of blood from finger, allow bubble to enter, and finally draw up a measure of bacterial suspension. Force out pipet contents on a clean slide, mix, withdraw a small drop to another slide, and with the edge of a clean slide make a smear.

5. Fix in alcohol, allow to evaporate, stain with eosin two minutes, and wash. Stain with methylene blue 30 seconds and wash until the eosin color reappears.

6. Count, using oil immersion lens. Count both r. b. c. and bacteria in each field until 1,000 r. b. c.'s are counted.

7. Compare suspension to turbidity standards, and estimate number of organisms present.

8. Make up vaccine to contain 1,000,000,000 bacteria per c. c.

#### CALCULATION

Lot X = No. bact. in suspension per cu. mm.

Lot Y = No. bact. counted, in this case 3,760.

5,000,000 = r. b. c. per cu. mm.

1,000 = r. b. c. counted.

1,000 : 3,760 :: 5,000,000 : X

1 c. c. contains 18,800,000,000 bacteria. Therefore, add 17.8 c. c. sterile solution to each c. c. of bacterial suspension; for, if

$$\begin{aligned} 18.8 \text{ c. c.} &= 18,800,000,000 \text{ bacteria,} \\ \text{then } 1 \text{ c. c.} &= 1,000,000,000 \quad \text{"} \end{aligned}$$

9. Make transplant using 0.5 c. c. to bouillon tube.
10. Add tricresol to vaccine sufficient to make 0.23 per cent.
11. Stopper vaccine with inverted sterile nipple.

## VI

### VITAL STATISTICS

**Estimate of Population.**—Example of arithmetical method.

Population of a city June 1, 1900, census 50,000

Population of same city April 15, 1910, census 61,850

Period between = 9 years  $10\frac{1}{2}$  months = 9.875 years.

Annual increase by arithmetical calculation:

$$\frac{61,850 - 50,000}{9.875} = 1,200 \text{ per year.}$$

Estimated for July 1, 1906: Period from 6—1—00 to 7—1—06 = 6 years, 1 month = 6.083 years =  $50,000 + (6.083 \times 1,200) = 57,300$ .

As a rule, population is estimated to July 1st for the year in which the statistics are being compiled.

**Formulae.**—General (crude) death rate =  $\frac{\text{No. deaths}}{\text{Population}} \times 1,000$

Corrected for non-residents:

$$\text{Resident death rate} = \frac{\text{No. deaths (residents)}}{\text{Population}} \times 1,000$$

Specific death rate for a disease:

$$\frac{\text{No. deaths from a specific disease}}{\text{Total population}} \times 100,000$$

Fatality rates in per cent.:

$$\frac{\text{No. deaths from a specific disease}}{\text{No. cases of the same}} \times 100$$

Morbidity rate, or incidence:

$$\frac{\text{No. cases of a specific disease}}{\text{Population}} \times 1,000$$

Infant mortality:

$$\frac{\text{No. deaths of children under 1 year}}{\text{No. births for year (Still-births not included)}} \times 1,000$$

General (crude) birth rate:

$$\frac{\text{No. births per year}}{\text{Population}} \times 1,000$$

**Problems.**—Data are given below for Pittsburgh, Pennsylvania. From them, calculate:

- (1) General (crude) death rate.
- (2) Death rate corrected to exclude non-residents.
- (3) The specific death rate of white and colored people.
- (4) Specific death rate for tuberculosis and typhoid.
- (5) Fatality rate for typhoid, etc.
- (6) Incidence of measles, typhoid, etc.
- (7) Infant mortality, general, white and colored.
- (8) The birth rate, general, white and colored.

## STATISTICS FOR PITTSBURGH, PENNSYLVANIA

Population			
Year	Total	White	Colored
1880 .....	156,381		
1890 .....	238,617		
1900 (as of June 1st) .....	451,512	430,973	20,355
1910 ( " " 15th) .....	533,905	508,008	25,623
1920 (est. July 1st) .....	588,193		

## Statistics for 1917

Deaths		Deaths From	
Total .....	10,645	Tuberculosis (Pulmonary):	
White .....	9,472	Total .....	753
Colored .....	903*	White .....	670
Non-Resident .....	1,278	Colored .....	83
		Typhoid:	
		Total .....	70
		Measles:	
		Total .....	63
No. of Cases of			
Typhoid .....	234		
Measles .....	4,031		
Tuberculosis (Pulmonary) .....	6,024		
Births		Deaths Under 1 Year	
Total .....	16,543	Total .....	1,983
White .....	15,889	White .....	1,846
Colored .....	655*	Colored .....	137

\* It will be noted the deaths colored exceed births. That this is not uncommon the following statistics show:

1919		1920 (1st half year)	
Deaths (colored)	788	Deaths (colored)	474
Births	703	Births	332

Number of cases estimated from total number of deaths from each disease and expected case fatality rates: Typhoid, 700; measles, 11,000; tuberculosis (pulmonary), 6,024. Incomplete reporting probably accounts for the difference between estimated number of cases and those actually reported. Use the estimated number of cases to compute case fatality rate.

(9) Fill out the enclosed death certificate with a primary and contributing cause of death.

(10) Fill out the enclosed birth certificate.

(11) Criticize the following causes of death:

Typhomalarial fever  
 Influenza  
 Fracture of skull  
 Rheumatism  
 Ptomain poisoning  
 Uremia  
 Gangrene  
 Cardiac dilatation  
 Cancer  
 Apoplexy  
 Paralysis  
 Convulsions  
 Hemorrhage  
 Peritonitis  
 Senility  
 Cerebrospinal meningitis  
 Appendectomy  
 Septicemia

Reference:—Physicians' pocket manual to the International List of Causes of Death. Bureau of the Census, Government Printing Office, Washington, D. C.

#### SIX RULES OF BERTILLON FOR PROPER CLASSIFICATION OF CAUSES OF DEATH

1. If one of the two diseases is an immediate and frequent complication of the other, the death should be classified under the head of the primary disease. Example:—

Scarlet fever and diphtheria, classify as scarlet fever.

2. If the preceding rule is not applicable the following should be used. If one of the diseases is surely fatal and the other is not of such gravity, the former should be selected as the cause of death. Example:—

Pulmonary tuberculosis and puerperal septicemia, classify as tuberculosis.

3. If neither of the above rules is applicable, then the following: If one of the diseases is epidemic and the other is not, choose the epidemic disease. Example:—

Measles and biliary calculi, classify as measles.

4. If none of the three preceding rules is applicable, the following may be used: If one of the diseases is much more frequently fatal than the other, then it should be selected as the cause of death. Example:—

Pericarditis and appendicitis, classify as pericarditis.

5. If none of the four preceding rules applies, then the following: If one of the diseases is of rapid development and the other is of slow development, the disease of rapid development should be taken. Example:—

Cirrhosis and angina pectoris, classify as angina pectoris.

6. If none of the above rules applies, then the diagnosis should be selected that best characterizes the case. Example:—

Saturnism and peritonitis, classify as saturnism.

## VII

### DIPHTHERIA DIAGNOSIS

#### COLLECTION OF SPECIMEN

*Material Necessary.*—(1) Sterile swabs—iron wire is better than wooden sticks. The latter may break, or if heavy enough, may be too thick to use in the nose.

(2) Clean slides.

(3) Tubes of Loeffler's serum medium.

*Method of Collection.*—The swab is rubbed gently but firmly against any visible membrane on the tonsils or pharynx, a rotary motion being given to the swab at the same time. The swab is immediately inserted in the blood serum tube and rubbed back and forth several times over the whole surface of the medium, again rotating the swab. Care should be taken not to break the surface of the blood serum. Then, from the same swab or from a fresh swab, make smears on a slide for direct examination. Return the swab to its tube and sterilize the whole.

It is advisable to take a culture from the nasal cavities after first cleansing them with a spray of sterile normal salt solution. It is well

to keep in mind that *B. diphtheriae* may cause infections of any of the mucous membranes, the order of incidence being pharynx, larynx, nasal cavities, conjunctiva, middle ear, and genital organs.

*Treatment of Specimen Collected*—Direct Smear.—Make three smears directly from the swab, dry them in air, fix and stain with Loeffler's methylene blue stain, Neisser's stain, gram stain. The absence of diphtheria bacilli must not be assumed if negative results are obtained, as they often pass unrecognized if mixed with a number of other organisms. Only if *numerous* gram positive bacilli, staining *irregularly* with Loeffler's methylene blue and showing typical granules with Neisser's stain, are obtained is one justified in making a diagnosis from direct smear. In all cases, culture should be resorted to for confirmation.

*Culture*.—Place the culture, made as above, at 37° C. as quickly as possible. If no incubator is available, an inside vest pocket will serve. On Loeffler's serum diphtheria bacilli usually outgrow all other throat forms (except staphylococci) within 18 hours.

*Examination of Culture*.—*B. diphtheriae* grows on Loeffler's serum media in large, round, elevated, yellowish or grayish-white colonies, with opaque center and an irregular periphery; the surface is moist. Remove some of the growth with a sterile platinum loop, and make a smear, dry, fix and stain with Loeffler's methylene blue. Neisser's stain and Gram stain. Animal inoculation may be resorted to to prove the presence of virulent diphtheria bacilli. This will be demonstrated.

#### THE SCHICK TEST

*Object*.—To determine the presence or absence of diphtheria antitoxin in the blood of the subject under test.

A minute quantity of toxin (1/50 M. L. D.) is injected *intracutaneously* and a local reaction follows if there is less than 1/30 of a unit of antitoxin per c. c. of blood. The explanation of the test is that when antitoxin is present, the toxin is neutralized and no injury to the tissues occurs. A negative reaction therefore indicates the presence of antitoxin (*immunity*). A positive reaction indicates the absence of antitoxin (*susceptibility*).

Diphtheria toxin is diluted so that 0.1 c. c. equals 1/50 of the M. L. D. for a 250-gram guinea-pig. This amount (0.1 c. c.) is injected with a 1 c. c. syringe and fine needle *intracutaneously* on the flexor surface of the forearm or arm. A good guide for the insertion of the needle into the proper layer of the skin is to be able to see the oval opening of the needle through the superficial layers of the epidermis. A properly made injection is recognized by a distinct wheal-like elevation, which moves with the skin, and shows the prominent openings of

the hair follicles. The results of the test should be read and noted daily.

The reaction that results at site of injection may be either positive, negative, pseudo, or combined positive and pseudo.

(1) *Positive*.—Trace of redness in 12 to 24 hours. Distinct in 24 to 48 hours. Reaches height on 3rd to 4th day. Leaves circumscribed scaling area of brownish pigmentation which persists for 3 to 6 weeks.

(2) *Negative*.—No reaction at site of inoculation.

(3) *Pseudo*.—Local anaphylactic response of the tissue cells due to the protein substances which are present in the toxic broth used for the test. Reaction appears early—in from 6 to 18 hours—reaches its height in 36 to 48 hours, disappears on the 3rd or 4th day. There is generally no scaling. At its height, the pseudo reaction shows varying degrees of infiltration and appears as a small central area of dusky redness with a secondary areola, which gradually shades off into the surrounding skin. The reaction may also have a rather uniform appearance and be two to three times the size of a true reaction. Compare with control.

(4) *Combined*.—Positive and pseudo reaction in the same individual. The central area of redness is larger and better defined, the amount of infiltration is also more marked, a definite area of scaling brownish pigmentation is observed after the pseudo element has disappeared in the test.

Pseudo, combined and doubtful reactions, in the absence of suitable controls should be regarded as positive to be on the safe side.

*Control*.—With toxin heated to 80° C. for 30 minutes, or with toxin neutralized with antitoxin, to help interpretation.

## VIII

### CLASSIFICATION OF PNEUMOCOCCI

Make smear preparations of pneumonia sputum. Stain for capsule by Hiss Method and Gram Method.

**Hiss Method**.—Preparations are made by mixing suspected material with a drop of animal serum, preferably beef blood serum, on a cover slip. Dry in air and fix by heat. Stain for a few seconds with fuchsin:

Saturated alcoholic fuchsin (or gentian violet) 5 c. c.

Distilled water

95 “

The cover slip is flooded with the dye and the preparation held over a Bunsen flame for a second until it steams. Wash off dye with 20 per cent. aqueous copper sulphate solution. Blot (do not wash), dry and mount.

**Isolation of the Pneumococcus—Avery's Medium.**—Meat infusion broth 0.3 to 0.5 per cent. acid to phenolphthalein containing 1 per cent. glucose and 5 per cent. defibrinated rabbit blood. This is distributed into test tubes in 5 c. c. quantities. A tube of this medium, or a mouse, is inoculated with washed sputum. The Avery's medium should be incubated 6 to 8 hours and the tube centrifuged at low speed to throw out blood cells. The supernatant fluid is tested in the same manner as described for peritoneal washings from the mouse. The Avery method is applicable only when mice are not obtainable.

Each group will autopsy the mouse inoculated the previous day with pneumonia sputum. The peritoneal cavity should be opened and the free fluid, if any, pipetted into a small test tube. The peritoneal cavity should then be washed with about 3 c. c. of sterile saline and the washings added to the peritoneal fluid. This gives a suspension of the organisms present in the peritoneal cavity. Plant cultures on blood serum from the hearts' blood and incubate. Make smear preparations from hearts' blood and stain as above.

Centrifuge the peritoneal washings for five to ten minutes at high speed. Pipet off (using capillary pipet) the clear supernatant fluid for use in the precipitin test. Resuspend the sediment in 3 c. c. salt solution for use in the agglutination test.

**Agglutination Test.**—Into five small tubes in a rack add as follows:

- |             |                                       |
|-------------|---------------------------------------|
| Tube No. 1— | 5 c. c. 1/30 dilution of Type I serum |
| “ “ 2—      | 5 c. c. undiluted Type II serum       |
| “ “ 3—      | 5 c. c. 1/10 dilution Type II serum   |
| “ “ 4—      | 5 c. c. 1/10 dilution Type III serum  |
| “ “ 5—      | 5 c. c. sterile ox bile               |

Add 0.5 c. c. of the bacterial suspension obtained from the peritoneal washing to each tube. Incubate at 37.5° C. for one hour. Note type of pneumococcus present and lysis in the bile tube. Record result.

**Precipitin Test.**—Into four small tubes in a rack add as follows:

- |             |                                       |
|-------------|---------------------------------------|
| Tube No. 1— | 5 c. c. 1/15 dilution of Type I serum |
| “ “ 2—      | 5 c. c. undiluted Type II serum       |
| “ “ 3—      | 5 c. c. 1/5 dilution Type II serum    |
| “ “ 4—      | 5 c. c. 1/10 dilution Type III serum  |

## IX

### MENINGOCOCCUS ISOLATION AND CARRIER DETECTION

Obtain material on a swab from the posterior nasopharynx (adenoid region); plate directly from the swab, and after 24 hours' incubation of the inverted plate, make presumptive slide agglutination tests with specific sera and suitable controls, using colonies fished directly from the

plates. The dried drops are later fixed and stained to determine whether the organism is a gram negative diplococcus. Where time and material are available, this technique is elaborated.

**Swabbing.**—In skilled hands the “open” swab may be successfully employed, but the use of the West tube is recommended. The swab must not touch lips, tongue, tonsils, etc. The mucous material on the tip of the swab is inoculated by touching the surface of the special medium in a Petri dish. The material is then spread over the surface with a platinum wire or it may be spread directly with the swab. The plates should be immediately incubated in the inverted position. Cooling of the plates and delay in incubation diminishes the number of successful isolations of the meningococcus.

**Examination of Plate Cultures.**—The colonies of the meningococcus are small and delicate. They are convex, glistening, translucent, and as they grow older tend to become opaque in the center. The young colonies may be confused with those of *Diplococcus crassus*, *Micrococcus catarrhalis*, *Diplococcus pharyngis flavus*, *Diplococcus pharyngis siccus*, and some *Streptococci*.

**Presumptive Slide Agglutination Test.**—Drop A is a 1/10 dilution of polyvalent meningococcus serum. Drop B is a 1/10 dilution of normal horse serum (control). Drop C is 0.85 per cent. salt solution (control).

A	B	C
O	O	O

Three drops are placed on a microscopic slide as shown. The suspected colony is fished and the platinum wire is dipped into each drop to permit part of the colony to wash off into it. In doing this, dip first into drop C, then into drop B, and finally into drop A. Burn the wire and after it has cooled, emulsify the material in each drop thoroughly working in the same direction. Agglutination in A and none in B and C is presumptive for meningococcus. Any other reactions are negative and indicate one of the other organisms. The slide can be stained by gram to verify the morphology and staining characteristics of the organism present.

**Macroscopic Agglutination.**—To 1 c. c. quantities of the emulsion in five tubes add:

- (1) To the first tube, 1 c. c. of a 1/100 dilution of normal type meningococcus serum.
- (2) To the second tube, 1 c. c. of a 1/100 dilution of parameningococcus serum.
- (3) To the third tube, 1 c. c. of a 1/50 dilution of Rockefeller polyvalent antimeningococcic serum.
- (4) To the fourth tube, 1 c. c. of a 1/10 dilution of normal horse serum (control).

(5) To the fifth tube, 1 c. c. salt solution (control).

Incubate at 37° C. for 3 hours.

**Interpretation.**—Agglutination in tubes 1 and 3 = meningococcus (normal).

Agglutination in tubes 2 and 3 = parameningococcus.

Agglutination in tube 3 = meningococcus (intermediary).

Agglutination in all tubes, in none, or in either of the two controls is negative for meningococcus.

A. Each student will take a West swab, and after swabbing the nasopharynx of his neighbor, plate the material as directed, and after marking the plate for identification, will put it in the incubator in the inverted position.

B. The student will at this point acquaint himself with the character of the meningococcus colonies by studying the plates of pure cultures of meningococci and plates containing mixed cultures.

C. Students will at this point make a series of macroscopic slide agglutination tests to acquaint themselves with the technique of the procedure, using colonies from the plates containing pure cultures of meningococci. They will then proceed to make fishings of suspicious colonies from the mixed plates, and having identified a colony by the presumptive test, they will fish it to a blood agar slant. Mark for identification and incubate.

D. Students will set up three sets of five tubes as directed and using the meningococcus emulsions marked X, Y, and Z, will determine to which group they correspond.

E. Study plates put in incubator at the previous period.

## X

### SANITARY SURVEY OF A CITY OR TOWN

Each student is required to make a sanitary survey of a city or town, based on the following outline, and submit a written report of the same. The report should consist of: (a) data, (b) interpretation of the facts, and (c) criticisms and recommendations. In order to receive credit this year, the sanitary survey must be handed in not later than May 15th.

*Introduction*—General description of the town including:

- (a) History
- (b) Geographical position
- (c) Topography
- (d) Climate

- (e) Geology
- (f) Population (number and constitution)
- (g) Urban, suburban or rural
- (h) Organization of the board of health
- (i) Other information about the town.

*Water.*—

- (a) The water shed—sources of pollution, methods of collection, storage, purification
- (b) An analysis of the water and its interpretation
- (c) Public or private wells
- (d) Examine a sample of the water in the laboratory.

*Sewage.*—

- (a) System of disposal—if purified or treated, how?
- (b) Efficiency
- (c) Relation to health of this and other towns
- (d) Criticism of system.

*Garbage, Refuse, Ashes.*—

- (a) Method of collection
- (b) Disposal
- (c) Relation to health
- (d) Criticism of methods.

*Vital Statistics.*—

- (a) Death rate
- (b) Infant mortality
- (c) Specific rates for:
  - (1) Typhoid
  - (2) Tuberculosis
  - (3) Measles
  - (4) Scarlet fever
- (d) Submit samples of blanks used by the department of health, especially those for deaths, births, marriages, and notifiable diseases. Fill out a death certificate. State opinion as to thoroughness of reporting morbidity, mortality and other vital statistics.

*Milk.*—

- (a) Report on the sanitary conditions of one farm and one city dairy, using score cards
- (b) Amount of milk pasteurized and by what method  
Criticism
- (c) Amount of milk "certified." If possible, visit and report on farm producing it.

- (d) Examine a sample of milk in the laboratory  
Interpret result.

*Sanitary Nuisances.*—

- (a) Source of odors
- (b) Dust—causes and method of prevention
- (c) Rubbish and general cleanliness. Empty lots. Dumps
- (d) Flies and mosquitoes
- (e) Rats and vermin
- (f) Stables and manure
- (g) Breeding places of mosquitoes
- (h) Smoke
- (i) Unnecessary noises
- (j) Piggeries, etc.
- (k) Legal definition of “nuisance” and method of abatement.

*Industrial Hygiene.*—

- (a) Report upon one industry based upon a visit to a factory or workshop.

*Housing.*—

- (a) Sanitary condition of one tenement
- (b) Ventilation of one large building.

*Communicable Diseases.*—

- (a) Give a list of the diseases notification of which is required by the board of health
- (b) Quarantine regulations
- (c) Methods of disinfection and fumigation
- (d) What measures are taken to prevent the spread of tuberculosis?
- (e) Should some other disease be prevalent, what measures are taken to control it?
- (f) Venereal diseases, reporting and control.

*Schools.*—

- (a) Visit and report on one school—ventilation, lighting, temperature, playgrounds, etc.
- (b) Medical inspection of school children. How conducted?
- (c) Diseases for which children are excluded from school.

*Miscellaneous.*—

- (a) Markets
- (b) Provision stores and soda fountains
- (c) Slaughter houses and meat inspection
- (d) Cold storage plants

- (e) Kitchens of hotels and restaurants
- (f) Wharves
- (g) Barber shops
- (h) Distribution of educational and other pamphlets
- (i) Other activities of the board of health, as maintenance of diagnostic laboratory, meat inspection, etc.
- (j) District nursing and social service
- (k) Charitable institutions or organizations of importance to public health such as Antituberculosis Association, Red Cross, Baby Hygiene, Milk Stations, Public Health Nursing, Health Center, Prenatal or Maternity Work, Hospitals for Communicable Diseases, and other health activities
- (l) City planning
- (m) Food and drug administration.

*General Summary of.*—

- (a) Conditions found
- (b) Criticisms
- (c) Recommendations.
